ABSTRACT

Electronic specific heat and residual resistivity measurements have been made on the $\text{Ag}_\alpha\text{Au}_{1-\alpha}$ binary and the $\text{Ag}_\alpha(60\text{at.}\% \text{Au}-40\text{at.}\% \text{Cu})_{1-\alpha}$ ternary disordered alloy systems as well as the two individual samples of $\text{Ag}_{0.5}(72\text{at.}\% \text{Au}-28\text{at.}\% \text{Cu})_{0.5}$ and $\text{Ag}_{0.5}(84\text{at.}\% \text{Au}-16\text{at.}\% \text{Cu})_{0.5}$. The residual resistances of the binary and ternary systems are found to obey Nordheim's rule only as a first approximation. Specific heat measurements on the binary system confirm previously published results. Two theories explain the latter either in terms of electron-phonon interactions or electron-impurity interactions. These theories have been extended to a ternary mixture of noble metals, where each predicts a different concentration dependence for the electronic specific heat. The measured results on the ternary alloys are compared with the analytical predictions to distinguish between the two processes involved.

I. INTRODUCTION

The study of the electronic properties of pure metals and intermetallic compounds has advanced significantly in recent years. With the wealth of available data and the agreement of the data with the theoretical calculations, it appears that we have a good qualitative as well as quantitative understanding of the electronic properties of these materials.

The same is not true in the case of disordered alloys. There has been much theoretical work in an attempt to describe the systems, but most of the work has been qualitative in nature with little hope of quantitatively comparing their predictions to experimental results. In addition, there is considerably less data available in the case of disordered alloy systems, since some of the more refined experimental techniques used in the investigation of pure metals and intermetallic compounds are not possible. The large increase in the scattering rate due to the disorder in the crystal lattice of bulk alloys prevents experiments which require $\omega_c \tau \gg 1$, such as the de Haas-van Alphen effect, from being performed. Therefore, it seems plausible that if quantitative as well as qualitative agreement between theory and experiment is to be obtained, it will probably be in one of the more simple alloy systems. Alloys of the noble

metals is one such system. Two possible measurements on the bulk alloys of this system are the specific heat and residual resistivity.

Nordheim¹, as early as 1931, attempted to explain the Ag-Au binary alloy residual resistance results in terms of perturbation theory. More recently the specific heat result of Green and Valladares² on this same system have been explained in terms of the electron-impurity interaction by Stern³, and the electron-phonon interaction by Haga⁴. Martin⁵ has also measured the specific heat of the Ag-Au system and extended the measurements to cover the entire alloy range. The present work is mainly concerned with measuring the specific heat and residual resistivity of the Ag-Au alloy series and examining the results in detail in terms of the two theories available. In addition, the theories and measurements have been extended to ternary Cu-Ag-Au alloys to test the validity of the theories in this regime and possibly to distinguish between the two physical processes involved in the explanation of the previous Ag-Au data.

II. ALLOYS-GENERAL DISCUSSION

Alloys of the three noble metals of copper, silver and gold form an interesting series for investigation. The Fermi surfaces of the pure metals are quite well known from de Haas-van Alphen and other data, and there is good agreement between this data and band structure calculations*. The pure metals have a band structure which is only slightly more complicated than the alkali metals, most of the Fermi surface being free-electron-like. The Fermi surface does contact the Brillouin zone faces in the $\langle 111 \rangle$ directions, but these are the only large distortions from a spherical shape.

Since the band structures of the three pure metals are all quite similar, one would not expect that the band structure of the isoelectronic alloys of these materials would differ drastically from that of the elements themselves. In fact, Faraday rotation experiments⁸ have been performed on the Ag-Au binary alloys and indicate that the area of contact of the Fermi surface with the Brillouin zone boundaries varies linearly from pure silver to pure gold. This means that the shape of the Fermi surface in the Ag-Au alloys can be calculated from an average potential and the properties of the alloys near the Fermi energy can be calculated by perturbation theory⁸. More recent de Haas-van Alphen measurements⁹

*See for example references 6 and 7.

on the dilute alloys of the Ag-Au system have cast some doubt on the results of the Faraday rotation experiments and complicate the analysis of even the most simple of alloy systems.

Metallurgically, the ternary alloys of Cu-Ag-Au form a continuous solid solution except for a eutectic region associated with the Cu-Ag rich portion of the ternary diagram¹⁰. All of the alloys crystallize in the face centered cubic structure, 'as in the pure metals, with an overall variation in lattice constant of only 10% over the entire ternary diagram¹¹. Of particular interest is the Ag-Au binary system where the variation in lattice constant is only 0.25% over the entire series.

The alloys of the noble metals are metallic and one expects the specific heat of these materials to behave as in other metallic substances. In particular, one expects a contribution from the excitation of electrons in the conduction band of a metal, which is linear in the temperature and is related to the density of electron states $N(E_F)$ at the Fermi level by the expression

$$C_{el} = \gamma T = \frac{\pi^2}{3} k_B^2 N(E_F) T \quad , \quad (1)$$

where k_B is the Boltzmann constant.

Another contribution to the specific heat is due to the lattice vibrations. In the Debye approximation, the phonon heat capacity per mole is given by

$$C_L = 9R \left(\frac{T}{\theta_D}\right)^3 \int_0^{\theta_D/T} \frac{z^4 e^z}{(e^z - 1)^2} dz, \quad (2)$$

Here R is the molar gas constant, and θ_D is defined through the relation $k_B \theta_D = \hbar \omega_D$, ω_D being the maximum cut-off frequency of the assumed normal mode spectrum. When $T \ll \theta_D$, the upper limit of the integral in (2) tends to infinity, giving at low temperatures

$$C_L = \frac{12 \pi^4 R}{5} \left(\frac{T}{\theta_D}\right)^3, \quad T \ll \theta_D. \quad (3)$$

The derivations of both the lattice and electronic specific heat expressions are well known^{12,13} and only the results are quoted above. Even at low temperatures, the Debye temperature computed by fitting the lattice specific heat to equation (3) begins to deviate from a constant value, indicating failure of the elastic continuum approximation and the departure of the phonon density of states from the Debye ω^2 dependence. Since it has been shown¹³ that under the proper choice of θ_D equation (3) is exact for any material at temperatures close to absolute zero, the density of phonon states is frequently written¹⁴ as an expansion in the even powers of ω . The next order contribution to the density of states is thus proportional to ω^4 and in calculating the lattice specific heat, the next order contribution is a

term proportional to T^5 . This term is frequently included in the fitting of metallic specific heat data to represent the deviation from the ω^2 frequency distribution.

There are two other possible contributions of the specific heat in the noble metal alloys. Gold possesses a nuclear electric quadrupole moment. In the pure metal there is no nuclear contribution to the specific heat at low temperatures because, in the cubic symmetry of the lattice, the nuclear levels are degenerate. However, in the disordered alloys, although the lattice-remains f.c.c., the cubic symmetry of the charge distribution is disturbed. The resulting electric field gradients split the degenerate nuclear levels and give rise to Schottky-type specific heat anomalies. The high temperature tail of such an anomaly can be represented to lowest order by a constant divided by T^2 . Such nuclear contributions have been observed at He³ temperatures in Ag-Au⁵ alloys and in Cu-Au alloys¹⁵. At He⁴ temperatures this effect is small and not observable.

There is another possible contribution to the specific heat which can seriously alter the results. This contribution can occur if transition metals in small quantities are added to the alloys. There has been much theoretical work to explain these effects and the

quantitative effects have been measured experimentally¹⁶ for typical transition metals which appear frequently as contaminants. For example, 2.3 ppm (by weight) of Fe in gold gives an apparent increase in the electronic specific heat coefficient of 3%. Therefore, it is necessary to be extremely careful in preparing noble metal alloys to prevent contamination of the alloys with transition metal impurities.

In the case of the resistivity of the alloys, it was first shown by Matthiessen¹⁷ that the increase in the resistance of a metal due to a small concentration of another metal in solid solution is in general independent of the temperature. The resistance is then the sum of a temperature independent part and a temperature dependent part. The temperature independent portion is the residual resistivity, which can be measured at very low temperatures where the temperature-dependent resistivity is zero. This resistivity arises solely from the disordered condition of the lattice structure of the alloys and is zero in a perfect crystal of a pure metal.

III. THEORY

As noted in Section II., Faraday rotation experiments on Ag-Au binary alloys indicate that the area of contact of the Fermi surface neck with the Brillouin zone boundaries varies linearly from pure silver to pure gold. This implies that the Fermi surface can be calculated from an average potential and that properties of the alloys near the Fermi surface can be calculated by perturbation theory. Two theories^{3,4} which make this assumption have been presented to explain the specific heat results of the Ag-Au binary alloy series². The two theories have been extended to include the ternary alloy system of Cu-Ag-Au and the basic assumption of an average potential has also been extended, although there is no direct confirmation in other than the Ag-Au alloys.

In all of the remaining calculations, it will be assumed that a ternary alloy is being considered. The results will hold equally as well in the case of the binary alloys by proper substitution of the atom fractions. The following notation will be adopted for the calculations: α = atom fraction of silver, $(1-\alpha)x$ = atom fraction of gold, $(1-\alpha)(1-x)$ = atom fraction of copper, $V_{Ag}(\underline{r})$ = potential of the silver ion, $V_{Au}(\underline{r})$ = potential of the gold ion, and $V_{Cu}(\underline{r})$ = potential of the copper ion.

The basic assumption of both theories is a perfect lattice with a potential at each lattice point, which is the average potential at a lattice point in the alloy. This periodic potential has the form

$$V_P(\underline{r}) = \alpha V_{Ag}(\underline{r}) + (1-\alpha) (xV_{Au}(\underline{r}) + (1-x)V_{Cu}(\underline{r})) \quad . \quad (4)$$

Using this periodic potential, the band structure of the alloy can be calculated to zero order. The resultant Fermi surface and density of states varies linearly between that of the pure constituents. The zero-order Bloch states for the crystal have the form

$$\psi_{\underline{k}}(\underline{r}) = N^{-\frac{1}{2}} U_{\underline{k}}(\underline{r}) e^{i\underline{k} \cdot \underline{r}} \quad , \quad (5)$$

where $U_{\underline{k}}(\underline{r})$ is normalized in a unit cell and has the periodicity of the lattice. The energy of a state \underline{k} to zero order is $E_{\underline{k}}$.

Both the theory of Haga⁴ and the theory of Stern³ can be obtained from the temperature dependent perturbation expansion for the total energy of a system of interacting electrons and phonons. The expansion gives^{4,18}

$$\begin{aligned}
E_{\text{Tot}} = & \sum_{\underline{k}} f_{\underline{k}} E_{\underline{k}} + \sum_{\underline{k}, \underline{q}} \frac{|V_{\text{ep}}(\underline{q})|^2 f_{\underline{k}} (1-f_{\underline{k}-\underline{q}}) (1+n_{\underline{q}})}{E_{\underline{k}} - E_{\underline{k}-\underline{q}} - \hbar\omega_{\underline{q}} + i\delta} \\
& + \sum_{\underline{k}, \underline{q}} \frac{|V_{\text{ep}}(\underline{q})|^2 f_{\underline{k}} (1-f_{\underline{k}-\underline{q}}) n_{\underline{q}}}{E_{\underline{k}} - E_{\underline{k}-\underline{q}} + \hbar\omega_{\underline{q}} + i\delta} \\
& + \sum_{\underline{k}, \underline{l}} \frac{|V_{\text{ei}}(\underline{l}-\underline{k})|^2 f_{\underline{k}} (1-f_{\underline{l}})}{E_{\underline{k}} - E_{\underline{l}} + i\delta}
\end{aligned} \tag{6}$$

where f and n are the Fermi and Planck distribution functions, respectively, and $V_{\text{ep}}(\underline{q})$ and $V_{\text{ei}}(\underline{l}-\underline{k})$ are the coupling constants for the electron-phonon and electron-impurity interactions and will be discussed in following paragraphs.

The energy of a quasi-particle, $E'_{\underline{k}}$, at the state of wave vector \underline{k} can be obtained by differentiating E_{Tot} with respect to $f_{\underline{k}}$ ¹⁹. At low temperatures both Haga and Stern neglect the imaginary part of the second and third terms in (6) to give

$$E'_{\underline{k}} = \epsilon_{\underline{k}} - i\Gamma_{\underline{k}} \tag{7}$$

$$\begin{aligned}
\epsilon_{\underline{k}} = & E_{\underline{k}} + \sum_{\underline{q}} |V_{\text{ep}}(\underline{q})|^2 \left[\frac{1-f_{\underline{k}-\underline{q}}+n_{\underline{q}}}{E_{\underline{k}}-E_{\underline{k}-\underline{q}}-\hbar\omega_{\underline{q}}} + \frac{f_{\underline{k}-\underline{q}}+n_{\underline{q}}}{E_{\underline{k}}-E_{\underline{k}-\underline{q}}+\hbar\omega_{\underline{q}}} \right] \\
& + \sum_{\underline{l}} \frac{|V_{\text{ei}}(\underline{l}-\underline{k})|^2}{E_{\underline{k}} - E_{\underline{l}}}
\end{aligned} \tag{8}$$

$$\Gamma_{\underline{k}} = \pi \sum_{\underline{k}} |V_{ei}(\underline{1}-\underline{k})|^2 \delta(E_{\underline{k}} - E_{\underline{1}}) \quad . \quad (9)$$

In Haga's analysis, the last term of equation (8) is neglected and only the electron-phonon interaction is considered as contributing to the real part of the energy. In Stern's analysis, the second and third terms in equation (8) are neglected and only the electron-impurity interaction is considered as contributing to the energy.

Virtual Crystal Approximation

In this section, Stern's analysis of the problem is extended to a ternary alloy of noble metals. The potential of the alloy can be written as

$$V(\underline{r}) = V_p(\underline{r}) + V_{ei}(\underline{r}) \quad , \quad (10)$$

where $V_p(\underline{r})$ is given by (4) and

$$V_p(\underline{r}) = \sum_{\underline{g}} \left[\alpha S(\underline{g}) + (1-\alpha) (xG(\underline{g}) + (1-x)C(\underline{g})) \right] e^{i\underline{g} \cdot \underline{r}} \quad , \quad (11)$$

$$V_{ei}(\underline{r}) = \int V(\underline{k}) e^{i\underline{k} \cdot \underline{r}} d^3\underline{k} \quad . \quad (12)$$

Here \underline{g} are the reciprocal lattice vectors, while $S(\underline{g})$, $G(\underline{g})$ and $C(\underline{g})$ are the \underline{g} th Fourier components of the potential from the silver, gold and copper ions respectively, and $V(\underline{k})$ is the \underline{k} th Fourier component of the alloy potential with the condition $V(\underline{g})=0$.

The matrix elements of $\langle \underline{k} | V_{ei}(\underline{r}) | \underline{l} \rangle$ can be calculated for a particular configuration of atoms and reduced to a sum of terms, including products of lattice sums and matrix elements of the constituent ionic potentials integrated over a unit cell. The product $\langle \underline{k} | V_{ei}(\underline{r}) | \underline{l} \rangle \langle \underline{l} | V_{ei}(\underline{r}) | \underline{m} \rangle$ can be calculated and involves products of the lattice sums and matrix elements. Since the calculation is done for a particular configuration of atoms and since the number of atoms is large, an average over all possible configurations of the atoms is representative of the disordered alloy. The lattice sums can be averaged and the correction to the energy calculated. A complete calculation is shown in Appendix A.

The result for a ternary alloy is given by

$$\epsilon_{\underline{k}} = E_{\underline{k}} + N^{-1} \sum_{\underline{l}} \frac{\alpha(1-\alpha) |\langle \underline{k} | V_A(\underline{r}) | \underline{l} \rangle|^2}{E_{\underline{k}} - E_{\underline{l}}} + N^{-1} \sum_{\underline{l}} \frac{(1-\alpha)x(1-x) |\langle \underline{k} | V_B(\underline{r}) | \underline{l} \rangle|^2}{E_{\underline{k}} - E_{\underline{l}}}, \quad (13)$$

where the principal value of the integral is taken to exclude the contribution from the states, which contribute to real scattering. The matrix elements in (13) are defined as follows

$$\begin{aligned}
\langle \underline{k} | V_A(\underline{r}) | \underline{1} \rangle &= \langle \underline{k} | x (V_{Ag}(\underline{r}) - V_{Au}(\underline{r})) + (1-x) (V_{Ag}(\underline{r}) - V_{Cu}(\underline{r})) | \underline{1} \rangle \\
&= \int e^{i(\underline{1}-\underline{k}) \cdot \underline{r}} U_{\underline{k}}^*(\underline{r}) V_A(\underline{r}) U_{\underline{1}}(\underline{r}) d^3 \underline{r} \quad , \quad (14)
\end{aligned}$$

and

$$\begin{aligned}
\langle \underline{k} | V_B(\underline{r}) | \underline{1} \rangle &= \langle \underline{k} | V_{Au}(\underline{r}) - V_{Cu}(\underline{r}) | \underline{1} \rangle \\
&= \int e^{i(\underline{1}-\underline{k}) \cdot \underline{r}} U_{\underline{k}}^*(\underline{r}) V_B(\underline{r}) U_{\underline{1}}(\underline{r}) d^3 \underline{r} \quad , \quad (15)
\end{aligned}$$

where the integration is taken over the volume of a unit cell. In the case of a binary alloy such as Ag-Au where $x=1$, then (13) reduces to

$$\epsilon_{\underline{k}} = E_{\underline{k}} + N^{-1} \sum_{\underline{1}} \frac{\alpha(1-\alpha) |\langle \underline{k} | V_{Ag}(\underline{r}) - V_{Au}(\underline{r}) | \underline{1} \rangle|^2}{E_{\underline{k}} - E_{\underline{1}}} \quad , \quad (16)$$

in agreement with the results of Stern.

Using the expression (13) for the energy, the density of states at the Fermi level and the coefficient of the electronic specific heat, γ , can be obtained giving

$$-\frac{\gamma - \gamma_0}{\gamma_0} = \alpha(1-\alpha) K + (1-\alpha)x(1-x) L \quad , \quad (17)$$

where γ_0 is obtained from the zero order density of states and

$$K = -(2\pi)^{-3} N^{-1} \frac{\partial}{\partial E_{\underline{k}}} \int \frac{|\langle \underline{k} | V_A(\underline{r}) | \underline{l} \rangle|^2}{E_{\underline{k}} - E_{\underline{l}}} d^3 \underline{l} \quad , \quad (18)$$

$$L = -(2\pi)^{-3} N^{-1} \frac{\partial}{\partial E_{\underline{k}}} \int \frac{|\langle \underline{k} | V_B(\underline{r}) | \underline{l} \rangle|^2}{E_{\underline{k}} - E_{\underline{l}}} d^3 \underline{l} \quad . \quad (19)$$

As before, this expression can be reduced to Stern's result for a binary alloy by the proper adjustment of the atom fractions.

Equation (9) shows that the electrons also have a transition probability $P_{\underline{k}} = 2\Gamma_{\underline{k}}/\hbar$, which results in a dc transport relaxation time given by²⁰

$$\frac{1}{\tau_{\underline{k}}} = v(2\pi\hbar N)^{-1} \int \left[\alpha(1-\alpha) |\langle \underline{k} | V_A(\underline{r}) | \underline{l} \rangle|^2 + \right. \\ \left. (1-\alpha)x(1-x) |\langle \underline{k} | V_B(\underline{r}) | \underline{l} \rangle|^2 \right] |v_{\underline{l}} E_{\underline{l}}|^{-1} (1-\cos\theta) dS_{\underline{l}} \quad (20)$$

where $\tau_{\underline{k}}$ is the relaxation time of an electron state \underline{k} , $dS_{\underline{l}}$ is an element of area in the Fermi surface at \underline{l} and cylindrical symmetry in the scattering about \underline{k} is assumed. Equation (20) shows that the relaxation

time, and thus the residual resistance, varies with concentration. In particular, for a binary alloy, they are proportional to $\alpha(1-\alpha)$ as first shown by Nordheim¹.

Electron-Phonon Enhancement Model

In Haga's analysis of the binary alloy, the Fourier transform of an atomic potential²¹ is used as the coupling constant in the electron-phonon interaction, viz.

$$V_P(\underline{q}) = N \int V_P(\underline{r}) e^{-i\underline{q}\cdot\underline{r}} d\underline{r} \quad (21)$$

Here N is the number of cells per unit volume, \underline{q} is the difference between the wave vectors of the initial and final states of an electron and $V_P(\underline{r})$ is the potential given by (4). Neglecting Umklapp processes, neglecting the \underline{q} dependence of $V_P(\underline{q})$ and considering only longitudinal phonons which obey the Debye approximation, one obtains

$$V_{ep} = V_P \left(\frac{\hbar q}{2NMs} \right)^{\frac{1}{2}} \quad (22)$$

where M is the ionic mass and s the velocity of sound.

The term $E_{\underline{k}}$ in the denominator of (8) is replaced with $\epsilon_{\underline{k}}$, the energy of the quasi-particle at the state of wave vector \underline{k} . This replacement makes equation (8) equivalent to the lowest order approximation of the

electron-phonon interaction as calculated by the Green function method^{22,23,24}. Again assuming the Debye approximation is valid for phonons, (8) can be integrated to give^{18,22}

$$\epsilon_{\underline{k}} = E_{\underline{k}} + \lambda_{ep} \frac{k_B \theta_D}{3} \left[\ln \left(\frac{\epsilon_{\underline{k}} - k_B \theta_D}{\epsilon_{\underline{k}} + k_B \theta_D} \right) + \right.$$

(23)

$$\left. \left(\frac{\epsilon_{\underline{k}}}{k_B \theta_D} \right)^3 \ln \left| \frac{\epsilon_{\underline{k}}^2}{\epsilon_{\underline{k}}^2 - (k_B \theta_D)^2} \right| - \frac{\epsilon_{\underline{k}}}{k_B \theta_D} \right]$$

where

$$\lambda_{ep} = \frac{m_e q_m^2 v_p^2}{8\pi^2 \hbar^2 N M k_F s^2} \quad (24)$$

Here m_e and k_F are the band mass and wave number at the Fermi level of an electron, q_m is the radius of the Debye sphere, θ_D is the Debye temperature and the electron energy levels are measured from the Fermi energy.

Using the energy of the quasi-particle, the density of states can be calculated. In the presence of the level broadening $\Gamma_{\underline{k}}$, which is assumed to be constant in the neighborhood of the Fermi level, the

density of states at the Fermi level $N(E_F)$, is given by

$$N(E_F) = \pi^{-1} \int_{-\infty}^{\infty} \frac{N(\epsilon_{\underline{k}}) \Gamma}{\epsilon_{\underline{k}}^2 + \Gamma^2} d\epsilon_{\underline{k}} \quad . \quad (25)$$

By substituting the density of states found from (23) into (25), the density of states at the Fermi level becomes

$$N(E_F) = N_0 \left(1 + \lambda_{ep} G\left(\frac{\Gamma}{k_B \theta_D}\right) \right) \quad , \quad (26)$$

$$G(y) = 1 - y^2 \ln\left(1 + \frac{1}{y^2}\right) \quad , \quad (27)$$

where N_0 is the zero-order density of states and is assumed to vary linearly between the pure constituents of the alloy. The density of states of the alloy, and thus the electronic specific heat, can be analyzed as a function of the level broadening due to the electron-impurity scattering. A complete derivation of the electron-phonon enhancement model appears in Appendix A.

IV. EXPERIMENT

Samples

The samples used in this work have been prepared by induction melting the proper amount of 99.999+% pure silver shot and gold spatter and 99.9999% pure copper rod in a graphite crucible under an inert helium atmosphere. During the melting process, the samples are held in their molten state for a period of time to ensure eddy-current mixing of the constituents. After casting, the binary Ag-Au alloys are cold worked, but the cold working is eliminated in the ternary alloys due to their extreme hardness in the as cast condition. All of the alloys are electrolytically etched in a 10% KCN solution using stainless steel electrodes and then sealed in evacuated vycor envelopes. The binary Ag-Au alloys are homogenized at 800°C for 72 hours and the ternary alloys at 725°C for 72 hours. All of the alloys are quenched in cold water after the homogenizing period.

The ingots are machined by cutting out an axial section for a resistivity specimen and tapping them at the top and bottom for attachment of the addenda for specific heat measurements. In addition, the ternary specimens all have an additional cylindrical section cut from the top of the ingot for future investigation. The resistivity specimens are machined

in the form of a parallelepiped of dimensions .100" x .100" x 1.25". In the machining operations, solid tungsten carbide taps, drills, tool bits, slitting saws and flycutters are used to prevent transition metal contamination of the samples. The binary Ag-Au alloy samples are given a final etch in KCN and are ready for measurement. Due to the extensive machining, the binary Ag-Au resistivity specimens are given a second heat treatment at 800°C for 72 hours with a subsequent quench before measurement. The ternary specific heat specimens are etched thoroughly to remove surface contamination and are sealed along with the resistivity specimens in evacuated pyrex ampoules. They are then heat treated at 425°C for 72 hours and quenched in cold water, so as to shatter the ampoules and to ensure a rapid quench.

The temperature of 425°C has been chosen for heat treating the ternary alloys, since it is slightly above the transition temperature for ordering of the equiatomic Cu-Au binary alloy. Very high temperature quenches have been avoided, since there is evidence in the literature^{15,25} that they can produce partial ordering. This ordering is due to quenched in vacancies and subsequent room temperature annealing. A complete phase diagram is not available for the ternary alloys, but it is assumed that the transition temperature as well as the tendency for ordering decreases rapidly as silver

is added to the Cu-Au binary. Therefore, the 425°C temperature is assumed to be above the transition temperature for all of the ternary alloys, yet not excessively high so as to produce significant ordering after the quench. The ternary specific heat alloys are given a final etch in KCN prior to measurement. All of the final specific heat specimens contain approximately two moles of material, to produce a significant specific heat for measurement.

Specific Heat Measurements

A standard calorimeter, based on a design by Manchester²⁶ employing a mechanical heat switch, has been used in all of the He⁴ specific heat measurements. The design of this calorimeter has been described previously²⁷ and is described in detail in Appendix C.

The sample and the attached addenda are suspended by nylon threads within the two vacuum cans of the calorimeter. The outer can is immersed in a He⁴ bath and both cans are held at a common vacuum of 5×10^{-7} mm Hg, the high vacuum seal of the outer can being provided by a gold O-ring. The inner can contains a small helium chamber, which is maintained at 1.2°K by pumping on the condensed helium with a small external pump. This inner can also contains the heat switch, which consists of two indium faced copper jaws connected thermally to the helium bath

with copper braid. The heat switch mechanism is pivoted on teflon bearings and is actuated by an actuating rod, which passes through the top of the probe and is raised and lowered manually. Both vacuum cans are suspended from the top of the calorimeter with thin wall stainless steel tubes. All of the tubes contain radiation shells and all electrical leads are thermally anchored to prevent stray heat leaks. The entire calorimeter is contained in a stainless steel dewar with a nitrogen heat shield.

Screwed into the top of the sample there is a .164" dia. x 1.375" long threaded copper rod to make contact with the jaws of the heat switch. A threaded Cu-Be cylindrical shaped boss is screwed into the bottom of the sample, the heater and thermometer assembly being clamped to this boss. The heater is wound from #50 insulated manganin wire and has a nominal resistance of 1782 ohms at 4.2°K. The lead resistance, with the heater removed, has been measured at helium temperature so that a correction can be applied to the data for the leads power. The heater currents, which in the experiments are either .22 ma or .5 ma depending on the sample specific heat, are generated by a constant current supply. Both the heater current and the integrated heat pulse given to the sample are measured with a Hewlett Packard 2401C Integrating Digital Voltmeter. The digital voltmeter and the heater are turned on simultaneously

with a simple gating mechanism, employing mercury wetted relays. The power supplied to the sample is given by, $\Delta Q = I_H \int_0^t V_H dt$, where I_H is the measured heater current and $\int_0^t V_H dt$ is the measured time integrated voltage developed across the heater.

Temperatures are measured with a CryoCal, Inc. four terminal encapsulated germanium resistor. The thermometer has been calibrated in the range 1.2 to 4.2°K against the 1958 He⁴ vapor pressure scale²⁸ with an error of less than .0005°K. A temperature versus resistance table has been generated at .01°K intervals and a Legendre polynomial interpolation scheme, using this table, is employed to find the actual temperature. The thermometer resistance measurements are made by standard d.c. techniques. The thermometer resistance is monitored with a #7536 guarded Leeds and Northrup potentiometer, using an Astrodata nanovoltmeter as a null detector. The out-of-balance voltage from the nanovoltmeter is monitored with a chart recorder to give continuous observation of both ΔT of a heating period and the drift rate of the sample due to heat leaks. A graphical extrapolation of this drift rate to the center of the heating period is used to remove the heat leak contribution. The temperature at the beginning and end

of the heating period is reduced to the null condition using the chart recorder data. The temperature increment, ΔT , has been chosen so that by using the finite difference approximation, $C(\bar{T}) = \Delta Q / \Delta T$, the resultant error of approximately $1/4 (\Delta T/T)^2$ remains less than .1% in the He^4 temperature range.

A detailed description of the procedure used in a specific heat measurement is given in Appendix D. The calorimeter is cooled to 77°K , with liquid nitrogen in the outer shield of the metal dewar and helium and hydrogen exchange gases in the inner dewar and inner and outer can, respectively. The hydrogen gas is then pumped out of the probe and liquid helium transferred into the inner dewar. The sample and the inner can are cooled to 4.2°K by condensing helium in the helium chamber of the inner can with the heat switch closed. After cool down, the temperatures of the outer bath and the inner helium chamber are lowered to 1.2°K by pumping on both. In this condition the helium lasts approximately 14-16 hours, so that normally, 150 data points can be taken in a single night. The data is reduced by hand initially and then fed to a computer for complete analysis. A least squares fit of the data is obtained in the He^4 region and various plots of the results are obtained.

Resistivity Measurements

The resistivity measurements are made by the standard four terminal method. All four contacts to the sample are made with .010" thick phosphor bronze material. The current is supplied to the sample, in series with a standard resistor, with a Hewlett Packard 6101A power supply. The voltages developed across the standard resistor and the sample are monitored with the Hewlett Packard Integrating Digital Voltmeter. A reversing switch in the circuit allows the current to be reversed, in order to adjust the data for thermal emfs. Measurements are made at the three fixed points of room temperature, nitrogen boiling point and helium boiling point. A more complete description of the apparatus is given in Appendix C.

The voltage developed across the standard resistor is used to calculate the current passing through the sample. The current along with the sample voltage determines the sample resistance. A traveling microscope is used to measure the voltage contact length, while the sample cross sectional area is calculated from the weight of the sample, its density and average length. The average length of the sample is measured with a traveling microscope, while the sample density is determined from the atomic weight of the alloy and the lattice constant. A two dimensional fit of the lattice constant has been made, which covers the entire ternary phase diagram and

produces lattice constants with an accuracy of .1%.

The total estimated accuracy of the resistivity measurements is 1.5%. A more complete description of the experimental procedure and data analysis is given in Appendix D.

V. EXPERIMENTAL RESULTS AND DISCUSSION

Resistivity Results

Table I shows the measured resistivities of the binary alloys, as well as the sample of pure silver and Table II shows the measured resistivities of the ternary alloys, as well as pure copper. The accuracy of all the resistivity values is discussed elsewhere and is 1.5%. The room temperature measurements involve another error, in that the samples have been measured at the ambient temperature of the dewar and have not been corrected to any standard temperature. Therefore, these values are quoted as being the resistivity at $295 \pm 3^\circ\text{K}$. In the remainder of the discussion, the values of the resistivity at 4.2°K will be referred to as the residual resistance.

Until recently, there have been no reliable data for the resistivity of the Ag-Au binary series for comparison with the present work. The values of the resistivity used by Nordheim were measured in 1911 by Beckman²⁹. These results were obtained at 20°C and were extrapolated to zero temperature by subtracting off a temperature-dependent resistance, which Nordheim assumed varied linearly between the room temperature resistivities of pure silver and pure gold. On the basis of this extrapolation, Nordheim concluded that the residual resistivity of the Ag-Au

alloys was symmetric in shape and could be described by the expression $\rho_0 = C\alpha(1-\alpha)$, where C is a constant and α is the concentration of silver. There is only fair agreement between the original room-temperature data and the present room-temperature values, with the maximum deviation being 10% at the equiatomic alloy. Thus there is a corresponding discrepancy between the present measured residual resistances and Nordheim's extrapolated values.

Linde also investigated the Ag-Au binary alloy system³⁰ but only at low concentrations of one noble metal dissolved in the other. These data show that one atom percent silver dissolved in gold produces the same change in resistivity as one atom percent gold dissolved in silver, namely $0.38 \mu\Omega\text{-cm/at.}\%$. Thus Linde's data support the conclusion of Nordheim that the residual resistivity curve for the binary alloys is symmetric in the constituents. Linde's measurements have been repeated at helium temperature for the case of Ag as the solvent³¹, but only recently has the experiment with Au as a solvent been repeated at helium temperatures. Boes et.al.³², in connection with experiments on the Kondo effect in Ag-Au-Yb alloys, have measured the resistivity of the Ag-Au binary alloy series at 77°K and 4.2°K . Their values are in complete agreement with the present work. The present data yield a change in residual resistance of $0.298 \mu\Omega\text{-cm/at.}\%$ for one atom percent

silver alloyed in gold and a change of $0.375 \mu\Omega\text{-cm/at.}\%$ for one atom percent gold alloyed in silver. Thus the symmetry of the measured resistivity changes is no longer exact.

Specific heat Results

Each specific heat run on a particular sample consists of taking approximately 150 data points between 1.3°K and 4.2°K in a single cool-down to helium temperatures. The data are least-squares analyzed and fitted to an expression of the form

$$C/T = \gamma + \beta T^2 + \delta T^4 \quad , \quad (28)$$

where γ is the coefficient of the electronic specific heat and β is related to the Debye temperature by the expression $\beta = \frac{12\pi^4}{5} R \left(\frac{1}{\theta_D} \right)^3$, R being the molar gas constant. Each data point is divided by the magnitude of the specific heat, so that fractional, rather than absolute, differences are minimized in the fit giving each data point equal weight. The results of such a fit are given in Table III for the binary Ag-Au alloy series and in Table IV for the ternary alloy specimens.

There are two distinct errors associated with these measured quantities. The first type of error results from uncertainties in the alloy compositions, statistical errors in the least squares determinations and uncertainties in the temperature resolution, etc., all of which can be

reasonably estimated. The second type of error is systematic in nature and is difficult to calculate. As long as internal consistency is observed with data taken in the same manner and with the same equipment, then it is only the first type of uncertainty which is important. Since these conditions have been observed for this series of measurements, the estimated errors are: 0.33% uncertainty in the γ values, 0.1°K uncertainty in the θ_D values and 50% uncertainty in the δ values. The total uncertainty, for comparison with data taken by other investigators, is perhaps double the estimated measurement errors due to the possibility of systematic errors.

There is generally good agreement between the present value of the specific heat coefficient for silver with those values of other investigators³³. In the case of gold, there is good agreement only with the most recent measurement by Martin¹⁶. As he has pointed out, this is probably due to the lack of high purity gold in past years and the effect of transition metal impurities on the determination of the specific heat.

The data for the Ag-Au binary alloys from the present work agree well with the measurements of Martin⁵ over the entire alloy range and reasonably well with the limited data obtained by Green and Valladares². A comparison of the present data with those of Martin points out the need

for internal consistency, in that there seems to be an almost constant error of approximately one percent in the γ values between the two sets of data. However, the relative values of γ compare well and the difference must be attributed to a difference in the systematic errors in the two sets of data.

Discussion

Figure 1 shows the residual resistivity results for the binary $\text{Ag}_\alpha\text{-Au}_{1-\alpha}$ and ternary $\text{Ag}_\alpha\text{-(60at.\% Au-40at.\% Cu)}_{1-\alpha}$ alloys. The resistivity of the binary and ternary alloys can be analyzed on the same basis as Nordheim¹ or Stern³. Referring to the expression for $1/\tau$ given by (20), it is assumed that the integrals of the two matrix elements involved are constant across the alloy series and that $1/\tau$, and thus the residual resistance, varies with concentration as

$$\rho_0 = \rho_0' + \rho_0'' = C\alpha(1-\alpha) + D(1-\alpha)x(1-x) \quad , \quad (29)$$

where C and D are constants and the concentrations of the three constituents are defined in Section III. For the binary Ag-Au alloys, $x=1$ and ρ_0'' is zero. A least squares fit of the data for the Ag-Au alloys to the relation given by (29) yields the value of $C = 35.06 \mu\Omega\text{-cm}$.

In the case of the ternary alloys, the term ρ_0'' of (29) is not zero but is linear in $(1-\alpha)$, varying from zero at the pure

Figure 1. The residual resistivity of $\text{Ag}_\alpha\text{-Au}_{1-\alpha}$ binary alloys and $\text{Ag}_\alpha(60\text{at.\% Au}-40\text{at.\% Cu})_{1-\alpha}$ ternary alloys.

silver end to a value of unity at the pure copper-gold alloy. For a copper-gold alloy with fixed concentrations of its constituents alloyed with silver, as in the case under consideration where $x=0.6$, the factor $x(1-x)$ does not introduce any further concentration dependence and ρ_0'' is shown by the dotted line in Figure 1. The concentration dependence of ρ_0' for the ternary alloys is also parabolic in $\alpha(1-\alpha)$ and is shown by the difference in the solid and dotted line of the ternary data in Figure 1. A least squares fit of the ternary resistivity data to equation (29) yields $C = 11.82 \mu\Omega\text{-cm}$ and $D = 11.19 \mu\Omega\text{-cm}$.

If one ignores the linear term ρ_0'' in the expression (29) for the ternary alloy and looks only at the parabolic portion ρ_0' it is in fact possible to predict the reduction in the term C for the ternary alloys from the term C for the binary alloys. Equation (14) shows the matrix element for the determination of C in the ternary alloy. This matrix element is an integral involving the sum of two terms, one depending on the differences between the silver and gold potential in a unit cell and the other on the difference between the copper and silver potential. The relative importance of these two terms can be determined from the binary residual resistance data³⁰ for the alloys of the noble metals, shown in Table V. Since the resistance change produced by the addition of copper to silver is

TABLE V.

Change in resistivity due to one atomic percent of one noble metal dissolved in another.

Alloy	$\Delta\rho$ $\mu\Omega\text{-cm/at.}\%$
Cu in Au	0.485
Au in Cu	0.55
Cu in Ag	0.068
Ag in Cu	0.140
Ag in Au	0.38
Au in Ag	0.38

much less than that produced by the addition of gold to silver, it can be seen that the matrix elements of the difference between the copper and silver potentials must be significantly smaller than the matrix elements of the difference between the silver and gold potentials. If it is assumed, in fact, that the matrix element of the difference between the copper and silver potentials is zero, one obtains the simple relation

$$C_{\text{Ternary}}/C_{\text{Binary}} = x^2 \quad , \quad (30)$$

where x is the concentration of gold in the copper-gold binary alloy being added to silver to form a ternary alloy. For the particular ternary series being considered, equation (30) yields $C_{\text{Ternary}}/C_{\text{Binary}} = 0.36$ while the experimental resistivity data yields $C_{\text{Ternary}}/C_{\text{Binary}} = 0.34$. There will be further consideration of equation (30) when the specific heat results are discussed.

Although it is possible to predict the major changes in the residual resistivity on these simple considerations, this treatment is only approximately correct. Thus if one ignores the linear term ρ_0'' in the ternary residual resistivity, equation (29) shows that $\rho_0'/\alpha(1-\alpha)$ should be independent of solute concentration. Figure 2 shows the concentration dependence of $\rho_0'/\alpha(1-\alpha)$ for the binary and ternary alloys. The results of Boes et.al. on the

Figure 2. $\rho'_0/\alpha(1-\alpha)$ for binary $\text{Ag}_\alpha\text{Au}_{1-\alpha}$ alloys and ternary $\text{Ag}_\alpha(60\text{at.\% Au}-40\text{at.\% Cu})_{1-\alpha}$ alloys.

binary Ag-Au alloys have been included to show the good agreement with the present work. Clearly Nordheim's rule for the binary alloys and the generalization of Nordheim's relation, represented by the term ρ_0' for the ternary alloys, is only obeyed as a first-order approximation since the curves are not completely flat. In particular, the asymmetry in the binary alloy data, as discussed in the comparison of the present data with those of Linde, is clearly evident.

There are several possible explanations for the deviations of the data from the generalized Nordheim's rule. To begin with, the possibility of scattering terms from higher order perturbation theory have been neglected in the analysis. Verboven has shown³⁴ for a binary alloy, that the third order term in the perturbation expansion for ρ is proportional to $\alpha(1-\alpha)(1-2\alpha)$. Again on the basis of a τ which varies across the alloy series only as the concentration dependence, the addition of a third term with the concentration dependence found by Verboven would considerably improve the fit to the present data.

The effects of band structure changes in going across the alloy series have been neglected. Dingle temperatures from de Haas-van Alphen measurements⁹, Hall effect data³⁵, and deviations from Mathiessen's rule³⁶ in noble metal alloys, all indicate that for impurity scattering, τ is

anisotropic. If the Fermi surface of the noble metals is divided into the two extreme regions of the neck where the electrons have p-like symmetry, and the larger belly region where the electrons have s-like symmetry, then the measurements above indicate that $\tau_{\text{Belly}}/\tau_{\text{Neck}} \approx .25$ to $.4$.

Ziman³⁷ has explained this effect in terms of the short-range effect of the perturbation on the lattice potential when isoelectronic materials are alloyed. The perturbed potentials are thus more effective in scattering the electrons with s-like symmetry which have their maximum amplitude at the lattice site, than the p-electrons which have their maximum amplitude between the lattice sites. Therefore, s-wave impurity scattering dominates in the determination of the resistivity. In going across the alloy series from pure silver to pure gold in the binary alloys and from pure silver to the copper-gold binary in the ternary alloys, the Fermi surface becomes less free-electron or s-like and more p-like. Therefore, one could expect a variation in $\rho_0'/\alpha(1-\alpha)$ simply because the relative number of s and p-states is varying across the alloy series. Unfortunately this cannot completely explain the alloy data, since there is a decrease in the value of $\rho_0'/\alpha(1-\alpha)$ when gold is added to silver in the binary alloys but an increase in the same quantity when the copper-gold binary is added to silver in the ternary alloys. This difference occurs even though both alloy systems have

the same trend towards less free-electron-like Fermi surfaces.

The ternary alloy data is further complicated by a change in the lattice constant, which has been neglected in the analysis. It is difficult to assess the effect of this lattice constant change on the ternary resistivities. For example, the measured volume derivatives of the residual resistivity $d\rho_0/d\ln V$ are of different signs³⁸ when copper and gold are added to silver and it is not possible to conclude what would happen in the case of a copper-gold alloy being added to silver.

Finally, contrary to the results of Faraday rotation experiments, de Haas-van Alphen data for the dilute Ag-Au binary alloys indicate that the simple constituent weighted potential may not be completely justified. These measurements indicate that for trace amounts of gold added to silver the area of contact of the Fermi surface with the Brillouin zone boundary is larger than the linearly interpolated value, while for trace amounts of silver added to gold the same quantity is smaller than the linearly interpolated value. On the basis of Stern's theory, the de Haas-van Alphen neck area varies as if the difference between $V_{\text{Ag}}(\underline{r})$ and $V_{\text{Au}}(\underline{r})$ is larger when gold is added to silver than when silver is added to gold. On this qualitative basis, the effective scattering potential at the gold end of the series would be smaller than that calculated

with the linearly varying periodic potential. On the basis of data analyzed with the average periodic potential one would then expect a possible assymetry in the data, with $\rho_0'/\alpha(1-\alpha)$ being larger at the silver than at the gold end of the alloy series. This conclusion is in agreement with the observed residual resistivity behavior. Since there are no de Haas-van Alphen data for the ternary alloys, a similar analysis is not possible.

Comparison of equations (17), (18), (19) and (20) shows that both $1/\tau$ and $(\gamma-\gamma_0)/\gamma_0$ are proportional to the same matrix elements. We can analyze the electronic specific heat data, following Stern and Martin, by assuming the expressions (18) and (19) are constant. With this assumption, equation (17) can be written

$$\gamma = \gamma_0' + \gamma_0'' = \gamma_0 \left[1 + L(1-\alpha)x(1-x) \right] + \gamma_0 K\alpha(1-\alpha) \quad (31)$$

Here K and L are constants and γ_0 is the zero-order density of states, which varies linearly between the pure constituents in agreement with the Faraday rotation experiments. In the expression (31), γ_0' is equal to γ_0 for the binary Ag-Au alloys since $x=1$.

Figure 3 shows the binary Ag-Au electronic specific heat data. The dotted line shows the linear variation of γ_0 and the solid curve is a least-squares fit of the data to an expression shown by (31) with $K = -0.138$. This

Figure 3. The electronic specific heat of $\text{Ag}_\alpha \text{Au}_{1-\alpha}$ binary alloys.

value of K is identical to Martin's value of -0.14 for the same alloys; the agreement shows the importance of internal consistency when comparing the values of the electronic specific heat. In the original analysis of Green and Valladares data for the silver-rich binary alloys of Ag-Au^2 , Stern used a γ value for pure gold measured by another investigator and obtained an incorrect value of $K = -0.33$.

Although the fit to the present data yields the same value of K that was found by Martin, there are some obvious differences in the data. In particular, the present work gives a significant deviation from parabolic behavior at the pure gold end of the alloy series. Martin measured two alloys in this range of composition, namely 90 and 95 atom percent gold in silver. His result for the latter specimen is in agreement with the variation found in the present work, while that for the former is consistent with an essentially parabolic behavior. Martin concluded, on the basis of a spectrographic analysis of the 95 atomic percent gold sample, that the sample was contaminated with transition metal impurities and on this basis made an adjustment in the γ value, which brought this data point into better agreement with parabolic behavior. In the present work, four data points have been obtained for this composition range and all indicate a systematic deviation

from the parabolic dependence, which could be explained on the basis of transition metal contamination. Although a spectrographic analysis of the specimens has not been made, all of the specimens have been prepared in a consistent manner and it is highly improbable that only these four specimens would be contaminated.

The ternary alloy electronic specific heat values are shown in Figure 4. The dotted line in the curve is the variation of γ_0' given in equation (31), where $L = -.0082$ is determined from the γ values of silver and the pure copper-gold alloy along with the corresponding values of γ_0 . The solid curve is a least-squares fit to $(\gamma - \gamma_0')/\gamma_0 = K\alpha(1-\alpha)$, which yields for the present data $K = -.019$. In order to determine γ_0 for the ternary alloys, the value of γ for copper has been assumed to be $0.7000 \pm .0023 \text{ mJ/mole}^\circ\text{K}^2$, as found in a previous experiment²⁷ with the present apparatus.

The values of K , determined from the binary and ternary alloys, can be compared in a similar manner to the residual resistivity data. In fact, if the assumption is again made that the matrix elements of the difference between the copper and silver potential are zero, then one obtains

$$K_{\text{Ternary}}/K_{\text{Binary}} = x^2 \quad (32)$$

where again x is the atom fraction of gold in the copper-gold alloy. Unfortunately, in testing the validity of this expression, one must compare fractional quantities since

Figure 4. The electronic specific heat of $\text{Ag}_\alpha(60\text{at.}\% \text{Au}-40\text{at.}\% \text{Cu})_{1-\alpha}$ ternary alloys.

K is a fractional deviation of the electronic specific heat and the ratio shown by (32) has a large uncertainty associated with it. This is to be contrasted to the case of the residual resistivity where absolute values are compared and the uncertainty is correspondingly smaller.

In addition to the ternary alloy series containing 60 atomic percent gold in copper, two other alloys have been measured to test the validity of (32) and (30). These two alloys contain 72 atomic percent gold in copper and 84 atomic percent gold in copper. The two copper-gold alloys were alloyed with 50 atomic percent silver to form a ternary alloy. The data from these two alloys as well as the data from the $\text{Ag}_{0.5}\text{-Au}_{0.5}$ and the $\text{Ag}_{0.5}\text{-(60at.\% Au-40at.\% Cu)}_{0.5}$ alloys have been used in the following analysis. The data are analyzed by taking the ratios of $\rho_o' \text{ Ternary} / \rho_o' \text{ Binary}$. From equation (29), we have

$$\frac{\rho_o' \text{ Ternary}}{\rho_o' \text{ Binary}} = \frac{C_{\text{Ternary}}}{C_{\text{Binary}}} \quad (33)$$

since the common factor $\alpha(1-\alpha)$ is the same for all four alloys. For the specific heat values, the ratios of $(\gamma_o''/\gamma_o)_{\text{Ternary}} / (\gamma_o''/\gamma_o)_{\text{Binary}}$ are formed, which from (31) yield

$$\frac{\frac{\gamma_o''}{\gamma_o \text{ Ternary}}}{\frac{\gamma_o''}{\gamma_o \text{ Binary}}} = \frac{K_{\text{Ternary}}}{K_{\text{Binary}}} \quad (34)$$

Again the common factor $\alpha(1-\alpha)$ has been eliminated since it is the same for all four alloys.

By comparing equations (33), (34) and equations (30), (32) we see that both of these ratios should be equal to x^2 for the ideal case of the difference between the silver and copper potentials being zero. Figure 5 shows the results of the analysis. The dashed curve shows the x^2 dependence of (30) and (32), while the data points are the ratios defined by (33) and (34). As expected, the normalized values do not fall exactly on the predicted curve, since the idealized difference condition is not exactly satisfied. However, there is surprisingly good agreement between the normalized values of the resistivity and the specific heat despite the large errors in the latter.

Again many effects have been neglected in the analysis of the electronic specific heat. Higher order scattering effects have been neglected, as well as variations in the lattice constant and effects of changes in band structure. Previously it has been concluded from de Haas-van Alphen data on noble metal alloys that the effective scattering potential near pure gold may in reality be smaller, in comparison to the effective scattering potential

Figure 5. Comparison of normalized values of ρ_0' and γ_0''/γ_0 as a function of the gold concentration in copper for $\text{Ag}_{0.5}(\text{Au}_x\text{Cu}_{1-x})_{0.5}$ ternary alloys.

near pure silver. Thus, since the matrix elements of this potential are the same in the expressions for both the resistivity and specific heat, the resulting deviations from the predicted behavior should be similar in both. Therefore, the de Haas-van Alphen data could also explain the deviations in the specific heat for compositions near pure gold.

Another explanation of the deviations of the electronic specific heat from the predicted dependence is related to the behavior of the d bands on alloying. Optical measurements⁽³⁹⁾ have shown that the energy at the top of the d bands varies considerably across the Ag-Au alloy series and is much closer to the Fermi level in gold than in silver. In his original analysis, Stern concluded that, if the matrix element of the scattering potential coupled from the s and p-states at the Fermi level to the d states below the Fermi level, there would be a positive contribution to K in equation (31). This contribution would destroy agreement with experiment. He therefore assumed that the matrix elements only coupled s and p-states. However, if there were a small amount of coupling to the d-states, one would expect this to be largest in gold, where the d-states are closer to the Fermi level. This could produce a variation in the magnitude of K across the binary alloy

series with K being less negative toward the gold end of the series. No optical data is available for the ternary alloys and therefore it is impossible to draw any conclusions concerning the variation of K in this series.

Despite these complications and the difficulty in assessing their relative importance, the present data show that the essential concentration dependences are predicted surprisingly well by the theory. This is probably due to the fact that the major contribution to the integrals of the matrix elements for the effective scattering potential are due to the s -states at the Fermi surface, with other variations in parameters appearing as smaller perturbations on the predicted shapes.

Haga's analysis of the electronic specific heat in terms of the electron-phonon interaction has also been applied to the present results. Unfortunately, in his original analysis of the Green and Valladares data for the Ag-Au system, Haga also used a questionable value of γ for gold. This perhaps led to better agreement between theory and experiment than is possible in the case of the present data.

Using $V_{ep} = 2/3E_F$ in equation (24), one can estimate that $\lambda_{ep} = .17$ and $.18$ for silver and gold, respectively. Therefore, making Haga's assumption that they are equal, we obtain from equation (26)

$$\gamma = \frac{\gamma_{Ag}}{1+\lambda_{ep}} [1+b(1-\alpha)] [1+\lambda_{ep} G(\gamma)] \quad , \quad (35)$$

where b is determined from the γ values of pure silver and pure gold. The quantity $y = \tau/k_B\theta_D$ in this equation is determined from the residual resistivity, which Haga assumed to obey Nordheim's rule. In the evaluation of y , a parameter, a , is included to represent the difference between $1/\tau$ obtained from the residual resistance and the scattering probability in the present problem. Therefore one can write

$$y = \frac{a\alpha(1-\alpha)\hbar}{2\tau k_B\theta_D} \quad (36)$$

where τ is calculated from $\rho_0 = m/ne^2\tau$.

Using the specific heat data, one can calculate for each data point the quantity

$$\lambda_{ep}(\alpha) = \frac{1+b(1-\alpha)-\gamma/\gamma_{Ag}}{\gamma/\gamma_{Ag} - [1+b(1-\alpha)]G(y)} \quad (37)$$

By varying the magnitude of a in equation (29) above, one can determine an optimal value where λ_{ep} becomes concentration independent. Haga's analysis gives $\lambda_{ep} = .074$ and $a = 0.8$.

The above calculation has been repeated using the present data for the binary alloys, except the actual concentration-dependent resistivity has been used instead of assuming Nordheim's rule. One obtains a fair fit to the data with $\lambda_{ep} = 0.05$ and $a = 0.4$. The results are

quite sensitive to the choice of the magnitude of a , but the above value seems unreasonably low. Haga himself indicated that its value should be close to unity. Again considering the results in the analysis of τ for impurity scattering in noble metal alloys, one concludes that the major contribution to τ is from the s -like electrons on the belly of Fermi surface. The belly regions of the Fermi surface comprise the major portion of the Fermi surface and the s -wave scattering is isotropic, so one would conclude that the level broadening is properly calculated for these states with a value of a which is close to unity.

Therefore, Haga's value of 0.8 for the magnitude of the parameter a has been assumed and the value of λ_{ep} adjusted so that the zero-order density of states passes below the lowest specific heat data point. The results are shown in Figure 6 with $\lambda_{ep} = 0.044$, as a function of varying a . An increase in λ_{ep} , which results in a decrease of the zero-order density of states, gives a worse fit to the data. Correspondingly a decrease in λ_{ep} , which raises the zero-order density of states gives a negative electron-phonon enhancement. Clearly such behavior is not reasonable. Therefore the above value of λ_{ep} is a reasonable estimate for the assumed value of a . One can see that no value of a , including a equal to 0.8, gives a particularly good fit to the data.

Figure 6. Fit of electron-phonon enhancement model to $\text{Ag}_\alpha\text{Au}_{1-\alpha}$ binary specific heat data.

This seemingly obtuse way of obtaining a fit to the binary data does not alter the qualitative results, when the theory is applied to the ternary specific heat data. With the above values of a and λ_{ep} for silver and the known resistivity of the ternary alloys, one can adjust the zero-order density of states to give the measured value of γ for the Cu-Au binary alloy. The level broadening in the Cu-Au binary alloy can be calculated from the resistivity data. It is found that the quenching of the electron-phonon interaction is almost complete, so that the zero-order density of states corresponds very closely to the actual measured value of γ at this point. Once the zero-order density of states is known, the remainder of the curve can be generated using equation (28).

The results of such calculations are shown in Figure 7. One expects an initial rapid decrease in the electronic specific heat as the Cu-Au binary alloy is added to silver, due to the quenching of the electron-phonon interaction. This behavior is not observed in the data. Such a discrepancy does not imply that the electron-phonon interaction is non-existent in these alloys, but rather the present data cannot be explained merely on the basis of the electron-phonon interaction as formulated by Haga. In this connection, it should be noted that the electron

Figure 7. Fit of electron-phonon enhancement model to ternary $\text{Ag}_\alpha(60\text{at.}\% \text{Au} - 40\text{at.}\% \text{Cu})_{1-\alpha}$ specific heat data.

phonon enhancement of γ for silver and gold is probably small, since there is close agreement between their band, optical and specific heat masses¹⁸.

Figures 8 and 9 show the Debye temperatures for the binary and ternary alloys respectively. The Debye temperatures differ by less than 5°K from the linearly interpolated value across the entire binary alloy series and by less than 3°K over the entire ternary alloy series. Some authors have used this small deviation from linearity as an argument for the electron-phonon interaction being small, however, it is not completely clear that this is valid.

Figure 8. The Debye temperatures of $\text{Ag}_\alpha\text{Au}_{1-\alpha}$ binary disordered alloys.

Figure 9. The Debye temperature of $\text{Ag}_\alpha\text{-(60at.\% Au-40at.\%)}_{1-\alpha}$ ternary disordered alloys.

VI. CONCLUSIONS

The experimentally determined residual resistances and electronic specific heats of the $\text{Ag}_\alpha\text{-Au}_{1-\alpha}$ binary alloy system, $\text{Ag}_\alpha\text{-(60at.\% Au-40at.\% Cu)}_{1-\alpha}$ ternary alloy system and the two samples of $\text{Ag}_{0.5}\text{-(72at.\% Au-28at.\% Cu)}_{0.5}$ and $\text{Ag}_{0.5}\text{-(84at.\% Au-16at.\% Cu)}_{0.5}$ have been explained in terms of the virtual crystal model of Stern and the electron-phonon enhancement model of Haga. The results cannot be explained quantitatively or qualitatively in terms of the electron-phonon interaction as formulated by Haga. The electron-impurity interaction and the virtual crystal model gives reasonable results with the simple assumptions of constant matrix elements and pure s-wave scattering. The effective scattering potentials have a dominant effect on the magnitudes of the specific heat and residual resistances, with other varying quantities appearing as smaller deviations from the theoretical functional forms.

It has been assumed that the Fermi surface in the alloys varies linearly between the pure constituents but this has only been verified by Faraday rotation experiments in the Ag-Au alloys. There is need for Faraday rotation experiment on more of the alloys considered to verify this assumption. Positron annihilation studies, which are also

sensitive to the cross sectional area of the Fermi surface, could also be used in these bulk alloys to investigate the variation in neck size.

Since the data seem to be consistent with the electron-impurity interaction, a first principles calculation of this interaction would be interesting. The pseudopotential form factors exist for all of the noble metals and it should be possible to perform the zero-order calculation, assuming an average periodic potential and then treat the electron impurity interaction with perturbation theory. Unfortunately, this requires a large amount of computer time, since a complete band structure calculation must be done for each alloy considered.

Pauli spin susceptibility measurements on the ternary alloys would also be interesting, since the results are proportional to the density of states at the Fermi level. Electron-phonon enhancement effects do not alter the density of states as measured by this method but the interpretation of the data is difficult due to other contributions to the total susceptibility.

VII. ACKNOWLEDGEMENTS

I would like to thank my thesis advisor, Dr. J. A. Rayne for his help and guidance throughout the course of my thesis work. Mr. H. Lefke deserves recognition for the extreme care that was exercised in the machining of the alloy specimens. Dr. Y. Yafet provided some helpful assistance with theoretical problems encountered in extending Stern's theory to ternary alloys. I would also like to thank Mr. T. Morris and Dr. S. Friedberg for their help and advice during a particularly trying period after the theft of some gold and silver material and samples.

To my wife, Peg, goes my special appreciation for her hard work and sacrifice during my graduate study and for the preparation of this manuscript. To my daughter, Lisa, goes my apology for having to do without a normal home life during her early years. I would also like to thank my parents, Mr. & Mrs. T. H. Davis, and my wife's parents, Mr. & Mrs. A. F. Brown, for their contributions to my family including both their financial help and their continued support and encouragement.

APPENDIX A. THEORY

The purpose of this section is to examine the effect of the electron-impurity and electron-phonon interaction on the electronic specific heat and residual resistivity of a ternary alloy of the noble metals. The calculation is an extension of the theories of Stern⁴ and Haga³, which have been applied to binary alloys of the noble metals.

The model considered is a perfectly disordered alloy with three constituents distributed at random on a perfect lattice. It is further assumed that, to zero order, the crystal can be represented as a periodic arrangement of potentials with the potential at each lattice point being the average potential at a lattice point in the alloy. This periodic potential is then of the form

$$V_P(\underline{r}) = \alpha V_{Ag}(\underline{r}) + (1-\alpha) \{ x V_{Au}(\underline{r}) + (1-x) V_{Cu}(\underline{r}) \} \quad (A1)$$

In this expression the symbols have the following meaning: α is the atom fraction of silver in the alloy, $(1-\alpha)x$ is the atom fraction of gold, $(1-\alpha)(1-x)$ is the atom fraction of copper, $V_{Ag}(\underline{r})$ is the potential of the silver ion, $V_{Au}(\underline{r})$ is the potential of the gold ion, and $V_{Cu}(\underline{r})$ is the potential of the copper ion.

Using this periodic potential, the band structure of the alloy can be calculated with the resultant Fermi

surface and density of states varying linearly between the pure constituents. The Bloch states to this order have the form

$$\psi_{\underline{k}}(\underline{r}) = N^{-\frac{1}{2}} U_{\underline{k}}(\underline{r}) e^{i\underline{k} \cdot \underline{r}} \quad , \quad (A2)$$

where $U_{\underline{k}}(\underline{r})$ is normalized in a unit cell and has the periodicity of the lattice. The energy of the state at \underline{k} to zero order is $E_{\underline{k}}$.

The starting point for the consideration of the two interactions being considered is the derivation of the total energy of a system of interacting electrons and phonons to second order in temperature dependent perturbation theory. The expression for the energy is^{4,18}

$$\begin{aligned} E_{\text{Tot}} = & \sum_{\underline{k}} f_{\underline{k}} E_{\underline{k}} + \sum_{\underline{k}, \underline{q}} \frac{|V_{\text{ep}}(\underline{q})|^2 f_{\underline{k}} (1-f_{\underline{k}-\underline{q}}) (1+n_{\underline{q}})}{E_{\underline{k}} - E_{\underline{k}-\underline{q}} - \hbar\omega_{\underline{q}} + i\delta} \\ & + \sum_{\underline{k}, \underline{l}} \frac{|V_{\text{ep}}(\underline{q})|^2 f_{\underline{k}} (1-f_{\underline{k}-\underline{q}}) n_{\underline{q}}}{E_{\underline{k}} - E_{\underline{k}-\underline{q}} + \hbar\omega_{\underline{q}} + i\delta} \\ & + \sum_{\underline{k}, \underline{l}} \frac{|V_{\text{ei}}(\underline{l}-\underline{k})|^2 f_{\underline{k}} (1-f_{\underline{l}})}{E_{\underline{k}} - E_{\underline{l}} + i\delta} \end{aligned} \quad (A3)$$

where f and n are the Fermi and Planck distribution functions respectively, and $V_{\text{ep}}(\underline{q})$ and $V_{\text{ei}}(\underline{l}-\underline{k})$ are the coupling constants for the electron-phonon and electron-impurity interactions.

The energy $E'_{\underline{k}}$ of a quasi-particle at the state of wave vector \underline{k} can be obtained by differentiating E_{Tot} with respect to $f_{\underline{k}}$ ¹⁹. At low temperatures, the imaginary part of the second and third terms in (A3) can be neglected, yielding

$$E'_{\underline{k}} = \epsilon_{\underline{k}} - i\Gamma_{\underline{k}} \quad , \quad (\text{A4})$$

$$\epsilon_{\underline{k}} = E_{\underline{k}} + \sum_{\underline{q}} |V_{ep}(\underline{q})|^2 \left[\frac{1 - f_{\underline{k}-\underline{q}} + n_{\underline{q}}}{E_{\underline{k}} - E_{\underline{k}-\underline{q}} - \hbar\omega_{\underline{q}}} + \frac{f_{\underline{k}-\underline{q}} + n_{\underline{q}}}{E_{\underline{k}} - E_{\underline{k}-\underline{q}} + \hbar\omega_{\underline{q}}} \right] \quad (\text{A5})$$

$$+ \sum_{\underline{l}} \frac{|V_{ei}(\underline{l}-\underline{k})|^2}{E_{\underline{k}} - E_{\underline{l}}}$$

$$\Gamma_{\underline{k}} = \pi \sum_{\underline{l}} |V_{ei}(\underline{l}-\underline{k})|^2 \delta(E_{\underline{k}} - E_{\underline{l}}) \quad . \quad (\text{A6})$$

If it is assumed, according to Stern, that the electron-impurity interaction dominates and that the second and third terms of (A5) are small, then we have what will be referred to in this analysis as the Virtual Crystal Model. If it is assumed, according to Haga, that the electron-phonon terms dominate and that the last term in (A5) is small, then we have what will be referred to as the Electron-Phonon Enhancement Model.

Virtual Crystal Model

The following analysis is an extension of Stern's

theory of the electron-impurity interaction to a ternary alloy of the noble metals. The expressions for the ternary alloy can be reduced to Stern's results for the binary alloy by proper substitution of the atom fractions of the constituents.

The potential of the alloy is written as

$$V(\underline{r}) = V_p(\underline{r}) + V_{ei}(\underline{r}) \quad , \quad (A7)$$

where $V_p(\underline{r})$ is given by (A1) and

$$V_p(\underline{r}) = \sum_{\underline{g}} \left[\alpha S(\underline{g}) + (1-\alpha) (xG(\underline{g}) + (1-x)C(\underline{g})) \right] e^{i\underline{g} \cdot \underline{r}} \quad , \quad (A8)$$

$$V_{ei}(\underline{r}) = \int V(\underline{k}) e^{i\underline{k} \cdot \underline{r}} d^3\underline{k} \quad . \quad (A9)$$

Here \underline{g} are the reciprocal lattice vectors; $S(\underline{g})$, $G(\underline{g})$ and $C(\underline{g})$ are the \underline{g} th Fourier components of the potential from the silver, gold and copper ions respectively, while $V(\underline{k})$ is the \underline{k} th Fourier component of the alloy potential with the condition $V(\underline{g})=0$. $V_{ei}(\underline{r})$ can be calculated as a superposition of the difference between the actual potential in the unit cells of the alloy and the assumed periodic potential $V_p(\underline{r})$, i.e.

$$\begin{aligned}
V_{ei}(\underline{r}) &= \sum_N \left[V_{Ag}(\underline{r}-\underline{R}_N) - V_P(\underline{r}-\underline{R}_N) \right] P_1 \\
&+ \sum_N \left[V_{Au}(\underline{r}-\underline{R}_N) - V_P(\underline{r}-\underline{R}_N) \right] P_2 \\
&+ \sum_N \left[V_{Cu}(\underline{r}-\underline{R}_N) - V_P(\underline{r}-\underline{R}_N) \right] P_3
\end{aligned} \tag{A10}$$

Here R_N are the positions of the lattice points and P_1 , P_2 and P_3 are factors which are 1 if the site being considered is silver, gold or copper respectively and are 0 otherwise.

The matrix elements $\langle \underline{k} | V_{ei}(\underline{r}) | \underline{1} \rangle$ can be formed and the integrals transformed back into a unit cell with the result

$$\begin{aligned}
&\langle \underline{k} | V_{ei}(\underline{r}) | \underline{1} \rangle = \\
&N^{-1} \left[(1-\alpha) \sum_N P_1 e^{i(\underline{1}-\underline{k}) \cdot \underline{R}_N} - \alpha \left(\sum_N P_2 e^{i(\underline{1}-\underline{k}) \cdot \underline{R}_N} + \sum_N P_3 e^{i(\underline{1}-\underline{k}) \cdot \underline{R}_N} \right) \right] \\
&\langle \underline{k} | V_A(\underline{r}) | \underline{1} \rangle + N^{-1} \left[(1-x) \sum_N P_2 e^{i(\underline{1}-\underline{k}) \cdot \underline{R}_N} - x \sum_N P_3 e^{i(\underline{1}-\underline{k}) \cdot \underline{R}_N} \right] \\
&\langle \underline{k} | V_B(\underline{r}) | \underline{1} \rangle,
\end{aligned} \tag{A11}$$

where

$$\begin{aligned}
\langle \underline{k} | V_A(\underline{r}) | \underline{1} \rangle &= \langle \underline{k} | x(V_{Ag}(\underline{r}) - V_{Au}(\underline{r})) + (1-x)(V_{Ag}(\underline{r}) - V_{Cu}(\underline{r})) | \underline{1} \rangle \\
&= \int e^{i(\underline{1}-\underline{k}) \cdot \underline{r}} U_{\underline{k}}^*(\underline{r}) V_A(\underline{r}) U_{\underline{1}}(\underline{r}) d^3 \underline{r}
\end{aligned} \tag{A12}$$

and

$$\begin{aligned} \langle \underline{k} | V_B(\underline{r}) | \underline{1} \rangle &= \langle \underline{k} | V_{Au}(\underline{r}) - V_{Cu}(\underline{r}) | \underline{1} \rangle = \\ & \int e^{i(\underline{1}-\underline{k}) \cdot \underline{r}} U_{\underline{k}}^*(\underline{r}) V_B(\underline{r}) U_{\underline{1}}(\underline{r}) d^3 \underline{r} \end{aligned} \quad (A13)$$

The square of this matrix element can be obtained by considering $\langle \underline{k} | V_{ei}(\underline{r}) | \underline{1} \rangle \langle \underline{1} | V_{ei}(\underline{r}) | \underline{m} \rangle$, which yields

$$\begin{aligned} \langle \underline{k} | V_{ei}(\underline{r}) | \underline{1} \rangle \langle \underline{1} | V_{ei}(\underline{r}) | \underline{m} \rangle &= \\ N^{-2} \left[(1-\alpha)^2 A + \alpha^2 (B+C+2D) - 2\alpha(1-\alpha)(E+F) \right] & \langle \underline{k} | V_A | \underline{1} \rangle \langle \underline{1} | V_A | \underline{m} \rangle \\ + N^{-2} \left[(1-x)^2 B + x^2 C - 2x(1-x)D \right] & \langle \underline{k} | V_B | \underline{1} \rangle \langle \underline{1} | V_B | \underline{m} \rangle \\ + N^{-2} \left[(1-x)(1-\alpha)E - (1-\alpha)x F - \alpha(1-x)(B+D) + \alpha x(D+C) \right] & \\ \left[\langle \underline{k} | V_A | \underline{1} \rangle \langle \underline{1} | V_B | \underline{m} \rangle + \langle \underline{k} | V_B | \underline{1} \rangle \langle \underline{1} | V_A | \underline{m} \rangle \right] & \end{aligned} \quad (A14)$$

In (A14), the quantities A, B, C, D, E, and F are various products of lattice sums and the probability functions P_1 , P_2 and P_3 . These sums have been calculated for a particular distribution of atoms. Because of the large number of atoms involved, the value of a physical quantity found by averaging over all possible distributions of the three constituents is representative of the disordered alloy. Therefore, the following equations show the quantities A through F along with their averages over all possible distributions of the atoms. The

averaging is shown in detail for the quantity A and the results are quoted for the remainder of the quantities. In the averaging process we have used the fact that $V_{ei}(\underline{q})=0$ and have therefore assumed that $\underline{l-k} \neq \underline{q}$ and $\underline{m-l} \neq \underline{q}$.

$$\begin{aligned}
 \langle A \rangle_{AVG} &= \left\langle \sum_M \sum_N P_1 P_1 e^{i(\underline{l-k}) \cdot \underline{R}_M} e^{i(\underline{m-l}) \cdot \underline{R}_N} \right\rangle_{AVG} = \langle P_1 P_1 \rangle_{AVG} \\
 &= \sum_{M \neq N} \sum e^{i(\underline{l-k}) \cdot \underline{R}_M} e^{i(\underline{m-l}) \cdot \underline{R}_N} \overline{P_1 P_1} + \sum_N e^{i(\underline{m-k}) \cdot \underline{R}_N} \overline{P_1} \\
 &= \sum_{M, N} \sum e^{i(\underline{l-k}) \cdot \underline{R}_M} e^{i(\underline{m-l}) \cdot \underline{R}_N} \overline{P_1 P_1} - \sum_N e^{i(\underline{m-k}) \cdot \underline{R}_N} \overline{P_1 P_1} \\
 &\quad + \sum_N e^{i(\underline{m-k}) \cdot \underline{R}_N} \overline{P_1} \tag{A15} \\
 &= \alpha(1-\alpha)N \delta_{\underline{m}, \underline{k}}
 \end{aligned}$$

Similarly we find

$$\begin{aligned}
 \langle B \rangle_{AVG} &= \langle P_2 P_2 \rangle_{AVG} = (1-\alpha)x(1-(1-\alpha)x)^N \delta_{\underline{k}, \underline{m}} , \\
 \langle C \rangle_{AVG} &= \langle P_3 P_3 \rangle_{AVG} = (1-\alpha)(1-x)(1-(1-\alpha)(1-x))^N \delta_{\underline{k}, \underline{m}} , \\
 \langle D \rangle_{AVG} &= \langle P_2 P_3 \rangle_{AVG} = -(1-\alpha)x(1-\alpha)(1-x)^N \delta_{\underline{k}, \underline{m}} , \\
 \langle E \rangle_{AVG} &= \langle P_1 P_2 \rangle_{AVG} = -\alpha x(1-\alpha)^N \delta_{\underline{k}, \underline{m}} , \\
 \langle F \rangle_{AVG} &= \langle P_1 P_3 \rangle_{AVG} = -\alpha(1-\alpha)(1-x)^N \delta_{\underline{k}, \underline{m}} .
 \end{aligned}$$

Substituting these averages into (A14) gives the expression for the energy of the quasi-particle, namely

$$\begin{aligned} \epsilon_{\underline{k}} = E_{\underline{k}} + E_2(\underline{k}) = E_{\underline{k}} + \sum_{\underline{1}} \alpha \frac{(1-\alpha)}{N} \frac{|\langle \underline{k} | V_A | \underline{1} \rangle|^2}{E_{\underline{k}} - E_{\underline{1}}} \\ + \sum_{\underline{1}} \frac{(1-\alpha)x(1-x)}{N} \frac{|\langle \underline{k} | V_B | \underline{1} \rangle|^2}{E_{\underline{k}} - E_{\underline{1}}} \end{aligned} \quad (\text{A16})$$

In this expression, the principal part of the sum is taken to exclude those states which contribute to real scattering. Using (A16), the density of states can then be calculated from

$$N(E) = \frac{1}{4\pi^3 V} \int \frac{dS}{|\nabla_{\underline{k}} \epsilon_{\underline{k}}|} \quad , \quad (\text{A17})$$

where V is the volume of the alloy, and the integral is over the constant energy surface in \underline{k} space, $\epsilon_{\underline{k}} = E$.

Stern assumes, following Jones⁴⁰, that $E_2(\underline{k})$ of (A16) depends only on $E_{\underline{k}}$. Then, substituting (A16) into (A17) yields

$$N(\epsilon_{\underline{k}}) = N_0(E_{\underline{k}}) \left[1 - \frac{\partial E_2(\underline{k})}{\partial E_{\underline{k}}} \right] \quad , \quad (\text{A18})$$

where $N_0(E_{\underline{k}})$ is the zero order density of states at $E_{\underline{k}}$. If the Fermi level in zero order is at $E_{\underline{k}}$, then in the alloy it will be at $\epsilon_{\underline{k}}$, and the electronic specific

heat coefficient will be given by

$$\gamma = \gamma_0 \left[1 - \frac{\partial E_2(\underline{k})}{\partial E_{\underline{k}}} \right] \quad , \quad (\text{A19})$$

where γ is the electronic specific heat coefficient in the disordered alloy and γ_0 is the zero-order coefficient which is proportional to the zero order density of states.

Using the expression for $E_1(\underline{k})$ given by (A16) and changing the sum into an integral, (A19) can be written as

$$\frac{\gamma - \gamma_0}{\gamma_0} = \alpha(1-\alpha)K + (1-\alpha)x(1-x)L \quad , \quad (\text{A20})$$

where

$$K = -\frac{1}{2\pi^3 N} \frac{\partial}{\partial E_{\underline{k}}} \int \frac{|\langle \underline{k} | V_A(\underline{r}) | \underline{1} \rangle|^2}{E_{\underline{k}} - E_{\underline{1}}} d^3 \underline{1} \quad , \quad (\text{A21})$$

and

$$L = -\frac{1}{2\pi^3 N} \frac{\partial}{\partial E_{\underline{k}}} \int \frac{|\langle \underline{k} | V_B(\underline{r}) | \underline{1} \rangle|^2}{E_{\underline{k}} - E_{\underline{1}}} d^3 \underline{1} \quad . \quad (\text{A22})$$

These expressions reduce to Stern's result for the binary Ag-Au alloy system if the atom fraction of copper is replaced by zero; that is, $x=1$.

The alloy electron states have a dc transport relaxation time to second order in perturbation theory,

which can be calculated from the scattering probability given by $P_{\underline{k}} = 2 \Gamma_{\underline{k}} / \hbar$ and equation (A6). $P_{\underline{k}}$ is the scattering probability of an electron at state \underline{k} and $\Gamma_{\underline{k}}$ is the level width of the electron state. The relaxation time is²⁰

$$\frac{1}{\tau_{\underline{k}}} = \frac{v}{2\pi\hbar N} \int \left[\alpha(1-\alpha) |\langle \underline{k} | V_A | \underline{l} \rangle|^2 + x(1-x)(1-\alpha) |\langle \underline{k} | V_B | \underline{l} \rangle|^2 \right] (1-\cos\theta) |v_{\underline{l}} E_{\underline{l}}|^{-1} dS_{\underline{l}}, \quad (\text{A23})$$

where $\tau_{\underline{k}}$ is the relaxation time of an electron state \underline{k} and $dS_{\underline{l}}$ is an element of area in the Fermi surface at \underline{l} . Cylindrical symmetry in the scattering about \underline{k} is assumed.

Electron-Phonon Enhancement Model

In Haga's analysis of the binary alloy, the Fourier transform of an atomic potential is used as the coupling constant in the electron-phonon interaction. For the ternary alloy under consideration, this gives

$$V_p(\underline{q}) = N \int V_p(\underline{r}) e^{-i\underline{q} \cdot \underline{r}} d\underline{r}. \quad (\text{A24})$$

Here N is the number of cells per unit volume, \underline{q} is the difference between the wave vectors of the initial and final states of an electron and $V_p(\underline{r})$ is the

potential given by (A1). Haga neglects the Umklapp processes, neglects the \underline{q} dependence of $V_P(\underline{q})$ and considers only longitudinal phonons which are assumed to obey the Debye approximation and obtains

$$v_{ep} = v_P \left(\frac{\hbar q}{2NM s} \right)^{\frac{1}{2}}, \quad (A25)$$

where M is the ionic mass and s the velocity of sound.

The terms $E_{\underline{k}}$ in the denominator of (A5) are replaced with $\epsilon_{\underline{k}}$, the energy of the quasi-particle at the state of wave vector \underline{k} . This replacement makes equation (A5) equivalent to the lowest order approximation of the electron-phonon interaction as calculated by the Green function method^{22,23,24}. Equation (A5) can be integrated to give^{18,22}

$$\epsilon_{\underline{k}} = E_{\underline{k}} + \lambda_{ep} \frac{k_B \theta_D}{3} \left[\ln \left(\frac{\epsilon_{\underline{k}} - k_B \theta_D}{\epsilon_{\underline{k}} + k_B \theta_D} \right) + \left(\frac{\epsilon_{\underline{k}}}{k_B \theta_D} \right)^3 \ln \left| \frac{\epsilon_{\underline{k}}^2}{\epsilon_{\underline{k}}^2 - (k_B \theta_D)^2} \right| - \frac{\epsilon_{\underline{k}}}{k_B \theta_D} \right] \quad (A26)$$

where

$$\lambda_{ep} = \frac{m_e q_m^2 v_P^2}{8\pi^2 \hbar^2 N M k_F s^2} \quad (A27)$$

Here m_e and k_F are the band mass and wave number of an electron at the Fermi level, q_m is the radius of the Debye sphere and θ_D is the Debye temperature.

Using (A27), the density of states can be found from its definition to be

$$N(\varepsilon_{\underline{k}}) = N_0(E_{\underline{k}}) / \frac{d\varepsilon_{\underline{k}}}{dE_{\underline{k}}} \quad , \quad (\text{A28})$$

$$N(\varepsilon_{\underline{k}}) = N_0(E_{\underline{k}}) \left[1 + \lambda_{ep} F\left(\frac{E_{\underline{k}}}{k_B \theta_D}\right) \right] \quad , \quad (\text{A29})$$

$$F(y) = 1 - y^2 \ln \left| \frac{x^2}{1-x^2} \right| \quad . \quad (\text{A30})$$

Here as before $N_0(E_{\underline{k}})$ is the density of states to zero order and varies linearly between the pure constituents. The level breadth, given by (A6) is related to the scattering probability of a quasi-particle at the state \underline{k} by

$$P_{\underline{k}} = 2 \Gamma_{\underline{k}} / \hbar \quad . \quad (\text{A31})$$

It is known that when the probability of staying in a state damps exponentially with time, a level is broadened into the Lorentzian type⁴¹. Using the Lorentzian form and assuming that $\Gamma_{\underline{k}}$ is constant in the neighborhood of the Fermi level, then the number of states between E and $E+dE$ is given by

$$N(E) dE = \frac{1}{\pi} \sum_{\underline{k}} \frac{\Gamma}{(\varepsilon_{\underline{k}} - E)^2 + \Gamma^2} dE \quad . \quad (\text{A32})$$

Therefore, the density of states at the Fermi level is written as,

$$N(E_F) = \pi^{-1} \int_{-\infty}^{\infty} \frac{N(\epsilon_{\underline{k}}) \Gamma}{\epsilon_{\underline{k}}^2 + \Gamma^2} d\epsilon_{\underline{k}} \quad (A33)$$

where $\epsilon_{\underline{k}}$ is measured relative to the Fermi level. By substituting (A29) into (A33) and integrating we obtain

$$N(E_F) = N_0 \left(1 + \lambda \exp G \left(\frac{\Gamma}{k_B \theta_D} \right) \right) \quad (A34)$$

where N_0 is the zero-order density of states and the function G is defined by

$$G(y) = 1 - y^2 \ln \left(1 + \frac{1}{y^2} \right) \quad (A35)$$

APPENDIX B. SAMPLE PREPARATION

As stated in the main text, the samples which have been prepared cover the complete binary $\text{Ag}_\alpha\text{-Au}_{1-\alpha}$ disordered alloy series and the $\text{Ag}_\alpha\text{-(60at.\% Au-40at.\% Cu)}_{1-\alpha}$ disordered ternary alloy series along with the two individual samples of $\text{Ag}_{0.5}\text{-(72at.\% Au-28at.\% Cu)}_{0.5}$ and $\text{Ag}_{0.5}\text{-(84at.\% Au-16at.\% Cu)}_{0.5}$. Figure B1. shows the phase diagram for the Ag-Au binary alloys which exhibit no tendency for long range ordering and therefore present little difficulty in sample preparation. In the case of the ternary alloys, no such complete phase diagram exists. A melting point curve, shown in Figure B2, is available in the literature¹⁰ and outlines a eutectic region associated with the copper-silver rich ternary alloys. The atom fractions of the constituents in the ternary alloys have been chosen to remain outside of this eutectic boundary. Although no complete ternary phase diagram exists, it is known from the copper-gold binary phase diagram, shown in Figure B3, that there must be a tendency for the ternary alloys to order. This should occur at low silver concentrations near the regions of the intermetallic compounds of copper-gold. In particular, (60at.% Au-40at.% Cu) forms the δ ordered phase below approximately 360°C , (72at.% Au-28at.% Cu)

Figure B1. Phase diagram of silver-gold binary alloy

Figure B2. Liquidus diagram for copper-silver-gold ternary alloy system

Figure B3. Phase diagram of copper-gold binary alloy

forms the δ ordered phase below approximately 120°C and (84at.% Au-16at.% Cu) shows no tendency for ordering. The methods used to ensure disordered solutions of the ternary alloys are discussed in the description of their preparation.

All of the material used in making the alloys has been purchased from American Smelting and Refining Company. The gold is in the form of 99.999+% pure gold spatter; the silver is in the form of 99.999+% pure silver shot; and the copper is in the form of $3/8$ " diameter rod and is 99.9999% pure. In making the ternary alloys, the copper rod is cut to the approximate size needed with a carbide saw and etched thoroughly in HNO_3 before weighing.

All of the alloys have been prepared by induction melting the proper amount of materials in a graphite crucible under an inert helium atmosphere. Figure B4 shows a schematic of the experimental apparatus. Very pure reactor grade graphite has been purchased from Union Carbide Corporation for use in the crucibles and has been machined with carbide tipped tool bits to the desired size. The machined crucibles for most of the samples are $1-1/2$ " O.D. x $1-3/16$ " I.D. x approximately 6" long. After machining, each of the crucibles is baked out for approximately one half hour at 100°C above the maximum temperature to be reached in the melting process. The support for the crucible consists of a mullite rod, which

Figure B4. Schematic diagram of induction melting apparatus

is surrounded by high temperature fire brick machined to a cylindrical shape to fit inside the vycor envelope. The bottom end of the 2" I.D. vycor envelope is sealed with a rubber stopper which contains a piece of glass tubing for admitting helium gas. The top of the envelope is necked down to 3/8" diameter and is bent at right angles to the axis of the envelope so as to prevent foreign material from dropping into the crucible. During the melting process, helium gas is constantly bubbled through an external oil reservoir.

To melt a sample, the crucible filled with the constituents is placed in the oven and helium gas is bubbled through the envelope until all of the air is displaced. The induction furnace is turned on and the power is slowly increased until all of the material within the crucible is molten. The molten solution is held above its melting point for 15 to 30 minutes. During this period, eddy current mixing ensures a homogeneous distribution of the constituents. After the mixing period, the power is slowly decreased until solidification occurs. The helium atmosphere is maintained until the sample returns to room temperature, then it is weighed and compared to the total constituent weight to determine if any significant contamination has occurred during the melting process. Following the formation of the initial ingot, the preparation of the binary alloys differs from that of the ternary alloys and they will be discussed separately.

The binary alloys are first cold worked in three perpendicular directions. The alloys are pressed between oil hardened tool steel plates and compressed in each direction to approximately 60 to 70% of their original length. The alloys are then drilled and tapped with a small 8-32 hole. Solid carbide drills and taps have been used in the preparation of all of the alloys as well as carbide tipped slitting saws and tool bits for machining operations. The small 8-32 hole allows a threaded stainless steel rod to be screwed into the sample to act as both a suspension mechanism and an electrode for purposes of electrolytic etching. The samples are etched in this case, as well as all other etches, in a 10% solution of KCN in water. The cathode consists of four equally spaced strips of stainless steel sheet placed around the sample. An etching current of approximately 2 amps is used and etching times are of the order of 3 to 5 minutes. With the surface contamination removed, the alloys are placed in an evacuated vycor ampoule and homogenized at 800°C for 72 hours. At the end of the homogenization, the samples are removed from the oven and quenched in cold water to retain the disorder. Using a carbide tipped slitting saw, an axial section is cut from the ingot large enough to produce a .100" x .100" cross section resistivity sample. This resistivity sample is machined using a carbide tipped flycutter to the desired cross section and the ends are

squared off. The remaining specific heat sample is machined flat on the top and bottom surface and then drilled and tapped top and bottom with 8-32 holes. The 8-32 holes allow mounting of the addenda as discussed in Appendix C. The specific heat samples are given a final etch and are then ready for measurement. Due to the extensive machining of the resistivity specimens, they are given another heat treatment, in vacuo, at 800°C for 72 hours and quenched in cold water before measurement.

The ternary alloy samples as cast are already so hard that they are impossible to cold work to any degree. They are therefore tapped with a small 8-32 hole and etched in KCN as in the case of the binary alloys. They are then sealed in an evacuated vycor ampoule and homogenized at 725°C for 72 hours after which they are quenched in cold water. The samples are machined, and in addition to the specific heat specimen and resistivity specimen taken from the binary alloys, a thin cylindrical section is cut from the top of the samples for possible metallographic analysis or diffractometer measurements. The specific heat samples are again etched in KCN to remove surface contamination. The specific heat specimens and resistivity specimens are then sealed in an evacuated pyrex envelope. This envelope breaks on quenching and ensures a rapid quench. There is some evidence in the literature^{15,25}

that in the case of copper gold binary alloys, which have a tendency to order, quenching from temperatures just below the melting point can produce a more ordered sample than quenching from just above the transition temperature. This is due to the fact that a high quench temperature quenches in vacancies and subsequent annealing can produce ordering. To avoid this problem the method used by Martin is employed. That is, all of the ternary alloys are heat treated and quenched in distilled water from 425°C, which is slightly above the highest ordering temperature in the copper gold binary series. After quenching, the specific heat specimens are again etched in KCN and are then ready for measurement along with the resistivity specimens.

Table BI shows some of the more important data involving the specimens which have been measured and Figure B5 is a photograph of the majority of the specimens which have been measured. The resistivity specimens are .100" x .100" x approximately 1.25" long and the specific heat specimens are approximately 1-1/4" diameter by 1-1/4" high. As the picture shows, all of the specimens are polycrystalline with the grain size in the alloys ranging from a very small value to approximately .200" in size. In the binary alloy series, the samples remain silver in color until approximately 50 at.% gold is added to silver and then the characteristic gold color is dominant. In the ternary series the colors range from

salmon at (60at.% Au-40at.% Cu) to a gold color at intermediate alloys and then to the silver color at the pure silver end.

Table BI. Alloy data

Alloy atom percent		Alloy constituent weights			Atomic weight (gms.)	Lat. const. (Å)	S.H. spec. weight (gms.)	S.H. spec. gram-moles

Back row is silver-gold binary alloy system and front row is copper-silver-gold ternary alloy system. Reading from left to right the samples are:

Back row: 98at.% gold-2at.% silver (ρ only), 95at.% gold-5at.% silver, 90at.% gold-10at.% silver, 82.5at.% gold-17.5at.% silver, 75at.% gold-25at.% silver, 50at.% gold-50at.% silver (ρ only), 30at.% gold-70at.% silver, 20at.% gold-80at.% silver, 10at.% gold-90at.% silver, 2at.% gold-98at.% silver (ρ only), 100at.% silver.

Front row: 60at.% gold-40at.% copper, 90at.%(60at.% gold-40at.% copper)-10at.% silver, 80at.%(60at.% gold-40at.% copper)-20at.% silver, 70at.%(60at.% gold-40at.% copper)-30at.% silver, 60at.%(60at.% gold-40at.% copper)-40at.% silver, 50at.%(60at.% gold-40at.% copper)-50at.% silver, 30at.%(60at.% gold-40at.% copper)-70at.% silver, 10at.%(60at.% gold-40at.% copper)-90at.% silver.

APPENDIX C. APPARATUS

Specific Heat Apparatus

The basic mechanical components of the apparatus can be broken down into three categories: the probe or calorimeter, the metal dewar and the supporting vacuum systems. Figure C1 shows the basic configuration of the calorimeter inside the metal dewar. The metal dewar is constructed of stainless steel, except where noted, and consists of the sections labeled A through D in the figure. Region A is a permanently sealed vacuum space isolating the liquid nitrogen bath from room temperature. Region B is the liquid nitrogen space which has a capacity of 7 liters. The bottom 30 inches of the inside wall of this section is made of copper to facilitate cooling of the top portion of the probe. Contact of the probe with the nitrogen bath is made by a set of springy copper fingers as shown in the drawing and discussed in subsequent paragraphs. Section C is an externally pumped vacuum space which isolates the nitrogen bath from the liquid helium bath. Region D, the inner helium dewar, has an overall depth of 41-1/2 inches and a liquid helium capacity of 7 liters.

The entire metal dewar is rigidly attached to a 100 pound cast iron base mounted on shock absorbers to reduce vibrations transmitted through the floor.

Figure C1. Overall view of metal dewar and calorimeter.

Vibrations transmitted along the pumping line for the inner dewar are also damped by means of two flexible rubber radiator hoses. The U-shaped section of the pipe between the two hoses is connected to a concrete block with a board attached to the bottom. The concrete block assembly is completely embedded in a 12" x 16" x 20" box filled with sand. The tension produced by the block in the sand, in conjunction with the flexible hoses, effectively reduces the pump vibration transmitted along the pumping line and thus reduces extraneous heating of the sample.

The pumping line for the main helium chamber, along with the remainder of the supporting vacuum systems, is shown in the schematic representation of Figure C2. The three inch diameter main pumping line is connected to a Heraeus E135 oil sealed mechanical pump. Changes in pumping speed can be obtained by use of the three inch Kinney bellows sealed valve, (V16), or two smaller Kerotest valves, (V18, V19). A manostat is also available for maintaining the constant pumping speeds necessary for any temperature calibrations.

The high vacuum system is necessary to ensure thermal isolation of the sample, requiring pressures on the order of 10^{-6} mm Hg in the calorimeter inner and outer can. This vacuum is obtained by use of a two inch Heraeus oil

Figure C2 External plumbing schematic

diffusion pump, with a Welch 1400 mechanical pump supplying the backing pressure. A water cooled baffle, together with a liquid nitrogen cold trap, prevent back streaming of the diffusion pump oil. Connection of the high vacuum system to the calorimeter is made by means of a flexible stainless steel bellows with Heraeus "Quick Fit" rubber O-ring connectors to minimize transmitted vibrations. The high vacuum pressures are monitored with a Heraeus Ionivac 2 ionization gauge and the backing pressure with a NRC thermocouple gauge. In the event of malfunctions, several safety devices are present in the high vacuum system. A thermostat has been installed on the cooling coils of the diffusion pump so that, in the event of a water failure, the heater on the diffusion pump is turned off. In the event of a power failure, a solenoid valve placed between the backing pump and the diffusion pump seals in the pressure on the high vacuum side. The spillover tank above the backing pump catches any oil which is forced up into the pumping lines. An electrical relay prevents the entire system from reactivating when the electrical power is restored.

The remaining vacuum system is for pumping on the liquid helium contained in the probe liquid helium chamber. The pumping line is connected to a Welch 1400 mechanical pump and isolation can be obtained with a

Veeco bellows sealed valve, (V3). The remainder of the plumbing in this section of the apparatus is for introducing exchange gas into the probe and for storing the helium gas which is condensed in the liquid helium chamber of the probe. Also shown in the diagram is the connection for the probe vapor pressure bulb to a set of external mercury and oil manometers.

The probe or calorimeter contains the sample, heat switch, refrigerant and the internal vacuum plumbing. Figure C3 shows the arrangement of the lower portion of the probe. The sample, as mentioned in Appendix B, is tapped on the top and bottom surfaces with a 8-32 hole. A 1-3/8" x .164" diameter copper rod, which is threaded over the bottom 3/8", is screwed into the top of the sample. The rod contains two small perpendicular holes for insertion of the nylon mounting threads and provides the means for contact of the sample with the jaws of the mechanical heat switch. Into the bottom of the sample is screwed a small 1/4" high x 1/2" diameter cylinder of Cu-Be with an integral 1/4" long 8-32 threaded section along the cylinder axis. The boss shoulders on the bottom surface of the sample and provides a place for clamping the heater and thermometer assembly. The heater and thermometer assembly is made of Cu-Be with the top portion being a clamp for attachment to the sample and the bottom portion containing a small tapered hole. A tapered brass coil form is

Figure C3. Lower portion of the calorimeter showing the outer can, vacuum lines, heat switch mechanism sample location and thermometer assembly.

pressed into this hole. A heater is wound on the outside of the coil form and a germanium resistance thermometer is lacquered inside the coil form using GE-7031 lacquer. On the very bottom of the assembly is a small screw for attachment of nylon threads to stabilize the sample when it is suspended in the probe. The entire assembly of sample plus addenda is suspended by nylon threads which are lacquered in place to a brass sample support frame. This frame can be removed from the probe if desired.

The heat switch assembly is also contained within the inner can. The jaws and arms of the switch are made of copper and pivot on teflon bearings to minimize frictional heating. The jaws are thermally anchored to the helium chamber with copper braid and are faced with indium following the suggestion of Manchester²⁶. This facing reduces the sticking with the thermal post and increases the cooling rate of the sample from liquid nitrogen temperature. The heat switch is operated by means of a teflon drum attached to the actuating rod. The vertical movement of the 1/8" diameter stainless steel actuating rod opens and closes the jaws of the heat switch. The actuating rod passes through the center of the helium chamber and is enclosed along its entire length by a concentric 1/4" diameter stainless steel tube, which is maintained at a common vacuum with the inner can. The actuating rod is thermally anchored to

the outer can by soldering a copper ring between the rod and the bellows, which in turn is soldered to the outer can. In addition, copper braid is soldered between the copper ring and the copper housing surrounding the bellows assembly.

The top of the inner can, which contains the liquid helium chamber and the vapor pressure bulb, is machined out of a single piece of copper to provide good thermal contact between the two chambers for calibration of the germanium thermometer against helium vapor pressures. The helium chamber is machined in the form of a ring and has the volume of 4.5 cm^3 . The pumping line for this chamber is made of 12 mil wall stainless steel tubing and increases in diameter from $1/8$ " to $1/2$ " at the top of the outer can and from $1/2$ " to 1" at the nitrogen heat shield. This variation in diameter maintains a high pumping speed which varies as $T^{-1/2}$ and $(\text{dia.})^4$ along the length of the probe. A 1" pumping line, separated from the probe by (V3) as shown in Figure C2, is attached to a Welch 1400 mechanical pump for pumping on the condensed helium in the chamber. The vapor pressure bulb has a volume of 0.68 cm^3 and is connected to the top of the probe with a $1/8$ " stainless steel tube. This tube is enclosed concentrically from the top of the outer can to the probe head with a sealed $1/4$ " diameter stainless steel tube. The helium bath, surrounding the outer can and this

tube, freezes out the trapped air providing a good vacuum and thus isolation of the vapor pressure line.

The brass inner can surrounding the sample and heat switch assembly can be attached in either of two ways. If it is necessary, as in thermometer calibrations, to have different pressures in the inner and outer can, then the inner can is attached with a vacuum tight Wood's metal seal. A common vacuum is permissible in a standard specific heat run, and in this case the inner can is merely screwed into place. The pumping lines for both the inner and outer can are 1/2" diameter stainless tubing from the top of the outer can to the nitrogen shield where they are enlarged to 5/8" diameter to the probe head. The pumping line from the outer to the inner can is 1/8" diameter stainless steel tube.

The nitrogen heat shield of the probe is approximately 30" above the bottom of the inner can. The pumping lines are soldered to a copper ring which in turn is soldered along its circumference to a set of copper springy fingers. These springy fingers contact the inside wall of the metal dewar. The point of contact occurs just above the point where the vacuum jacket begins separating the nitrogen bath from the helium bath. This provides thermal contact of the heat shield with the 77°K liquid nitrogen at this point.

All of the pumping lines are provided with radiation shields, which are thermally anchored to the top of the

outer can and thus the surrounding helium bath. These shields, which are designated by S in Figure C3, are made of copper and consist of overlapping plates soldered into a copper cylinder similar to a venetian blind. The baffles are in turn soldered into the stainless steel lines at the top of the outer can.

The brass outer can is attached to the probe by means of 20 equally spaced Allen head screws around its circumference. A gold O-ring is squeezed between the copper beryllium surfaces of the outer can and the top of the outer can. A vacuum tight seal is obtained by gradually and successively tightening the 20 screws in a clockwise or counter-clockwise direction until further tightening becomes extremely difficult. The gold O-ring is made from .030" diameter chemically pure gold wire. The wire is cut to the required length and the ends are held together in compression with a small jig while they are fused together with a small torch. The resulting beaded junction is filed back to its original diameter and the entire O-ring is annealed with a soft flame.

All electrical connections to the inner can pass through a 14 pin vacuum sealed connector at the probe head and are fed through nylon spaghetti. These leads are passed down a 1/8" stainless steel tube to the top of the outer can. A section of this stainless tube, just above the top of the outer can, has been cut out and

replaced with a coiled section of 3/16" diameter soft copper tubing. The coiled tubing, sitting in the helium bath, acts as a radiation baffle for the electrical leads line, which is kept at a common vacuum with the outer can. Thermal anchoring of the leads takes place just inside the outer can where they are soldered to short insulated sections of copper wire which are in intimate thermal contact with the top of the outer can. Further thermal anchoring is provided by wrapping the coiled leads around the bellows housing and lacquering them in place. The leads are fed into the inner can through individual type Stupakoff feed-through terminals soldered into the top of the inner can. The coiled leads inside the inner can are tied and lacquered with nylon thread to the brass support frame and are then attached to the heater and thermometer respectively.

The circuitry used to measure the temperature of the sample using a germanium resistance thermometer is shown schematically in Figure C4. As mentioned previously, the Cryocal Inc. four terminal encapsulated germanium thermometer is cemented into the addenda assembly using GE-7031 lacquer. The thermometer leads are connected to the vacuum tight Stupakoff terminals in the top of the inner can using coiled #37 gauge manganin wire. From the Stupakoff connectors, coiled #40 gauge copper wire is wound

Figure C4. Block diagram of thermometer circuit

around the bellows housing as a heat sink and soldered to the insulated copper terminals at the top of the outer can as shown in Figure C3. The connections from this thermal anchor to the 14 pin connector are also made with #40 copper wire enclosed in nylon spaghetti. Low thermal solder is used in all of the solder connections which involve the measurement of the voltage drop across the thermometer.

The germanium resistance thermometer was calibrated in the range 1.2°K to 4.2°K against the 1958 He^4 vapor pressure scale²⁸ at the Westinghouse Research Laboratories by Dr. J. A. Rayne. For approximate use, the resistive temperatures were fit to an equation of the form:

$$\log T_R = a + b(\log R) + c(\log R)^2 . \quad (\text{C1})$$

The coefficients in equation (C1), for the temperature range of interest, are: $a=2.95749$, $b=-1.00170$, $c=0.080088$. The deviations of the true temperature, as determined by the helium vapor pressures, from the resistive temperature T_R , are plotted as $T-T_R$ versus T_R in Figure C5. For reduction of actual data, a smooth curve has been drawn through the deviation plot data of $T-T_R$ and a table has been generated to give the actual temperature versus the resistance at intervals of approximately $\Delta T \approx .01^{\circ}\text{K}$. The actual temperature equivalent to a resistance value is then determined from the table by Lagrangian interpolation.

Figure C5. Deviation plot of $T - T_R$ versus T_R for the germanium thermometer

The current source for the germanium thermometer is a standard 6 volt storage battery with the output controlled by the series of three resistances as shown in Figure C4. The 0-10M and 0-1M are divided in 10 steps and the 100 K resistor is a 10 turn Borg micropot. A thermometer current of 2 microamps is used at helium temperatures with the current increasing gradually to 1 milliamp at room temperature. The current is measured as a voltage drop across a Leeds and Northrup 1000 ohm secondary standard resistor. The original accuracy of this resistor of .05% has been increased to .001% by recalibrating it with a NBS type primary resistance standard. This recalibration has been completed with the resistors directly in the final circuit and using the same measuring equipment as used to measure the thermometer currents. The 25 microamp meter can be set to full scale readings of 2500, 250, and 25 microamps for coarse current adjustments. A 6K dummy resistor is placed in the circuit so that when the thermometer current is turned off in the 1000 ohm standard, the battery is not open circuited and only a short time is required for stabilization of the battery when it is switched back into the circuit. A Leeds and Northrup guarded six dial potentiometer is used to measure the thermometer current and thermometer voltages. Maximum readings of the potentiometer on its three scales are 1.6 volts, .16 volts and .016 volts with steps of 1,

0.1 and 0.01 microvolts respectively. A 120 amp hr. 6 volt low discharge Willard battery is used as the working cell for the potentiometer. The low discharge working battery, Eppley standard cell, null detector and connecting lead wires are all individually guarded to prevent current leakage paths and are highly insulated from ground. A copper box encloses the standard cell and low discharge battery and another box encloses the thermometer current supply battery to act as electrostatic shields along with the potentiometer case. An Astrodata Model 121 A d.c. nanovoltmeter is used as a null detector and gives a 3 volt signal for a full scale reading on any sensitivity setting. This output signal is reduced by a 300:1 voltage divider and supplied to a Leeds and Northrup Speedomax W strip chart recorder for monitoring the potentiometer out-of-balance voltages.

A schematic representation of the heater circuit is given in Figure C6. The sample heater is wound from #50 gauge manganin wire and has a resistance of 1782.84 ohms at 4.2^oK. Coiled #37 gauge manganin wire is used to connect the heater to the Stupakoff connectors in the inner can. The resistance of these leads has been measured at 4.2^oK and a correction is made for this lead resistance under the usual assumption that half of the leads power is conducted to the sample. The total lead resistance is 30.93 ohms giving a power correction factor of 99.15% of the power going to the sample. The four

Figure C6. Block diagram of heater-timer circuit

heater leads soldered to the top of the two Stupakoff connectors are #40 gauge copper wire and are wired in a similar manner to the thermometer leads. The heating current is generated with a Electronic Measurements Model C612 constant current supply which has a current regulation better than .1% and less than a millisecond transient response time for recovery from a step change of 0-100 volts. Heating current, for the samples measured, is either .22 ma or .5 ma depending on the temperature and sample specific heat. Heating times are kept below 45 seconds. The heater current is measured as a voltage drop across a Leeds and Northrup 100 ohm secondary standard resistor. This resistor has been recalibrated with a NBS primary standard resistance in the final circuit and using the same measuring equipment that is used to measure the actual currents. The resultant value for the resistor was $99.938 \pm .001$ ohms. The Hewlett Packard Model DY-2411A Guarded Data Amplifier and DY-2401C Integrating Digital Voltmeter, which are externally programmed by external closures to ground, are used in two different functional modes as controlled by switch S2. In the MILLIVOLT mode the digital voltmeter reads the thermometer current I_H across the 100 ohm resistor. This measurement is taken immediately after the heating period of a data point. In the VOLT SEC mode S2 switches the input leads of the digital voltmeter across the potential leads

of the heater. When S4 is closed to ground the voltmeter is gated to read the time integral of the heater voltage V_H until the gate S4 is again opened. The power supplied to the sample is calculated as $\Delta Q = I_H \int_0^t V_H dt$ which can be corrected for the heater leads power. The time integration of the voltage technique includes any change in the heater resistance due to over heating of the heater resistor during a heating period. This effect is quite small at helium temperatures.

S3 and S4 are mercury-wetted relay contacts. When S1 is closed, 6.5 volts from a Zener regulated power supply is switched across the clutch of an electric timer and across the energizing coils of the two relays, S3 and S4. When the make-before-break switch S3 is opened, current begins flowing through the heater resistor. At the same time, the break-before-make switch S4 closes the gate on the digital voltmeter to ground which starts integrating the heater voltage. By means of a simple circuit, the lapse in time between the two switch operations of S3 and S4 has been measured and found to be approximately 1 msec. on either opening or closing. This time difference produces a negligible error in the measurements.

A simple d.c. Wheatstone bridge circuit is used to measure the helium level in the metal dewar. The circuit

diagram for the depth gauge is shown in Figure C7. Three 47 ohm 1/10 watt carbon resistors are placed at three locations along the probe and are used as sensors for the depth gauge. When the helium level passes the carbon resistor, there is a large change in resistance due to the cooling, which is seen as a large step in the meter reading. The sensing resistors are enclosed in micarta to prevent them from being cooled excessively by the helium vapors and thus giving false meter readings. Connections to the bridge are made through a 7-pin hermetically sealed Winchester connector at the top of the probe.

Resistivity Apparatus

The resistivity measurements are made by the standard four terminal method. The .100" x .100" x 1.25" long samples are placed on the platform of the micarta tip of the measuring probe and held in place by the current and voltage contacts. All four of these contacts are made of .010" thick phosphor bronze material. The current contacts clamp the sample at its extremities and the voltage contacts, which have been filed to a pointed contact, clamp the sample at two points approximately 3/8" apart in the center of the sample. The other end of the four contacts are each clamped between two small copper blocks. The lead wires are soldered to one of these two copper blocks. The #36 gauge copper wires for the current leads pass to the top of the probe and are terminated at a Winchester

Depth Gauge

Figure C7. Depth gauge circuit

hermetically sealed connector. The two #36 gauge copper voltage leads are passed through individual Stupakoff seals at the top of the probe and are terminated at the guarded data amplifier low thermal plug. Low thermal solder is used at all connections of the voltage leads to keep thermal emf's at a minimum.

Figure C8 shows a schematic representation of the measuring circuit. The current is supplied by a Hewlett Packard 6101A d.c. power supply. The current is fed through a junction box to a reversing switch and then through a standard resistor and the sample. The standard resistor has been calibrated with another primary standard resistor and found to be .033099 ohms. The voltages developed by the sample are fed through the guarded data amplifier to the digital voltmeter. The voltage developed across the shunt is also passed through the guarded data amplifier to the digital voltmeter.

The probe and sample are placed in a standard nitrogen jacketed helium dewar. Resistivity measurements are made at the three fixed temperatures of room temperature, liquid nitrogen boiling point and liquid helium boiling point.

Photographs of various portions of the experimental apparatus are shown in Figures C9 to C12.

Figure C8. Schematic of resistivity measurement circuit

Figure C9. Photograph showing the external connections to the probe sitting in the metal dewar. The high vacuum system is shown at the left with the flexible metal bellows and quick fit connections. The dewar metal base is shown at the bottom and the dewar pumping line with the radiator hose and sand box damping system is shown behind the dewar. At the extreme right is shown the He_4 storage tank, and below it the Welch pump used to pump on the liquid helium in the helium chamber.

Figure C10. Photograph showing the probe with the outer can held in place by the 20 Allen head screws at bottom, the micarta enclosures for the depth gauge resistors just above the can, the copper springy fingers about three quarters of the way up the probe, and the vacuum connections and valves at the top of the probe.

Figure C11. Photograph of the bottom portion of the probe with the outer and inner can removed. An alloy sample with the attached addenda is shown suspended from the brass cage and the jaws of the heat switch are closed on the copper rod. Also shown are the Stupakoff type feed throughs into the inner can and the thermal anchoring at the top of the outer can.

Figure C12. Photograph of the experimental station used for specific heat measurements. Shown from left to right are: the high vacuum system including the Welch backing pump, oil diffusion pump, nitrogen cold trap, and the thermocouple and ionization gauges; the metal dewar with its steel base; rack no. 1 containing the L and N potentiometer, nanovoltmeter, electric clock, and the constant current supply; and rack no. 2 containing the Hewlett Packard amplifier and integrating digital voltmeter and the L and N chart recorder.

APPENDIX D. EXPERIMENTAL PROCEDURE AND DATA REDUCTION

Specific Heat Measurements

The first section of this appendix is devoted to a detailed description of a typical experimental run to measure the specific heat of a specimen from 1.3 to 4.2^oK. Where the procedures are dependent on the specimen specific heat, they are introduced paranthetically to the basic procedure. Also, certain malfunctions occur frequently and the alternate procedures to correct these malfunctions are introduced paranthetically. All valve labeling refers to the schematic representation in Figure C2 of Appendix C.

Initial System Configuration

1. Following valves closed: V1, V2, V3, V4, V5, V6, V7, V8, V11, V12, V13, V14, V16, V17, V18, V19, V20, V21, V22 and V23.
2. Following valves open: V9, V10 and V15.
3. Welch mechanical pump supplying backing pressure to diffusion pump running.
4. Welch mechanical pump attached to probe helium chamber running.
5. Diffusion pump running with cold water in water baffle and cooling coils and N₂ cold trap filled.
6. E-135 mechanical pump turned off.
7. Helium storage tank filled with He gas to pressure of 5 psi.
8. Probe heat switch closed.

Day 1

1. Clean and weigh specimen.
2. Attach addenda to specimen by screwing copper rod into top of specimen and copper beryllium boss for thermometer clamp into bottom of specimen.
3. Suspend specimen from cage in inner can by means of nylon threads inserted through the copper rod and lacquered to the cage with GE-7031 lacquer.
4. Attach thermometer to specimen by clamping to copper beryllium boss on bottom of specimen.
5. Complete suspension of specimen by tying nylon threads from thermometer clamp to four locations on the cage separated by 90° and lacquering them in place on the cage. Extraneous heating due to vibrations can be reduced to a minimum by ensuring that there is adequate tension on all of the nylon threads suspending the specimen in this procedure. Also frictional heating, which occurs when the heat switch jaws are opened at low temperatures, can be reduced to a minimum by ensuring that the copper rod is properly centered in the jaws of the heat switch.
6. Tie off the electrical leads to the cage with nylon thread and lacquer the nylon in place so that the leads do not contact the specimen or interfere with the attachment of the inner can.

7. Check the continuity of the electrical circuits.
The heater portion of the circuits can be checked with a Simpson meter while the thermometer portion should be checked with the potentiometer.
8. Screw the inner can to the probe.
9. Make a gold O-ring and carefully anneal this ring with a gas torch just prior to attachment of the outer can.
10. Affect O-ring seal between outer can and probe.
11. Place probe in metal dewar and connect external plumbing.
12. Check that working battery of L and N potentiometer is turned on. Under normal operation of the calorimeter, this battery is left on at all times since it requires three to four days to stabilize.
13. Pump the inner and outer can overnight with high vacuum system.
 - a. Close V9.
 - b. Open V1, V2 and V7.
 - c. When pressure is less than 100 microns Hg as indicated on thermocouple gauge, open V9 and close V7.
 - d. Open V8.

Day 2

1. Inner and outer can pressure should now be $4-8 \times 10^{-6}$ mm Hg as read by ionization gauge. (If the pressure is significantly higher, there is probably a leak in the gold O-ring seal. The probe vacuum should be sealed off by closing V1 and V2, the probe removed from the metal dewar and connected to a leak detector so that the O-ring seal can be checked for leaks).
2. Evacuate helium chamber in metal dewar.
 - a. Close V15.
 - b. Turn on E-135 mechanical pump.
 - c. Open V16.
 - d. When mechanical pump is quiet close V16 and vent pump.
3. Admit helium gas through V15 until pressure in helium chamber is slightly greater than one atmosphere as determined by pop-off valve in pumping line.
4. Admit a small amount of hydrogen exchange gas into the vacuum space between the helium and nitrogen chambers of the metal dewar by means of the small Veeco valve on the top of the metal dewar.

5. Evacuate the probe helium chamber and the gas line to the storage tank.
 - a. Open V3, V4, V5, V12 and V11.
6. Admit between 15 and 25 pipettes of H₂ exchange gas into the probe inner and outer can.
 - a. Close V1, V2 and V5.
 - b. Successively open V11, close V11, open V12 and close V12 until the desired number of pipettes is obtained.
 - c. Open V6 and then close.
7. Pump out H₂ gas from gas lines.
 - a. Open V5, V12 and V11.
8. Pressurize gas lines to 5 psi with helium from storage tank to prevent air leakage into gas lines.
 - a. Close V5.
 - b. Open V14 and then close.
 - c. Close V11 and V12.
9. Fill liquid nitrogen chamber of metal dewar. From this point on, the nitrogen shield should be filled every 3-4 hours until the run is completed.
10. Approximately 5-7 hours are necessary to reach 77°K. This is equivalent to a thermometer voltage of 6.39 to 6.41 mv. with a 1 ma current.

11. Remove H₂ exchange gas from the inner and outer can of probe.
 - a. Close V8 and V9.
 - b. Open V1, V2 and V7 until pressure on thermocouple gauge is less than 50 microns Hg.
 - c. Open V9, close V7 and open V8 in that order.
 - d. Pump for 8-12 hours.
12. Close V3 and V4 before leaving laboratory.

Day 3

1. Pressure should be $1-3 \times 10^{-6}$ mm Hg on ionization gauge. (If the pressure is significantly higher then there is again the possibility of a leak in the gold O-ring. The leak detector should be attached as a backing pump to the diffusion pump in place of the Welch mechanical pump. Leaks can be detected by alternately evacuating the helium chamber of the metal dewar with the E-135 mechanical pump and then filling the chamber with helium gas through V15.)
2. Rough out H₂ exchange gas in vacuum space between the nitrogen and helium chambers of the metal dewar with a Welch mechanical pump for approximately 30 minutes.
3. Use diffusion pump of leak detector to final pump this vacuum space for approximately 30 minutes.

4. Make first helium transfer. (The timing of this transfer depends on the specific heat of the sample being measured. For gold with a $\theta_D = 160^\circ\text{K}$, approximately 36 hours is required to reach 4.2°K . For copper with a $\theta_D = 345^\circ\text{K}$ less than 24 hours may be required.)
 - a. Pressurize helium chamber of metal dewar to one atmosphere by admitting helium gas through V15.
 - b. Monitor pressure of inner and outer can with ionization gauge: the pressure may rise by a factor of 2 initially due to warm gases but should fall to initial value in less than a minute. Any abnormal pressure rises which do not subside very quickly can indicate a leak.
 - c. Retighten heat switch since differential thermal expansion has a tendency to loosen jaws on copper rod attached to sample.
 - d. Open V15 before transfer tube is inserted.
 - e. When transfer begins open V16 to allow gases to escape through vent on E-135 mechanical pump.

- f. Transfer helium for 1-1/2 to 2 minutes after the level passes R_H , or the highest resistor on the depth gauge.
5. Condense 2 storage cans of helium gas at 20 psi into the helium chamber of the probe.
 - a. With V3 and V4 closed admit helium gas through V13.
 - b. Open V14 and V11 and pressurize tank to 20 psi.
 - c. Close V13, open V5 and using V12 throttle gas into helium chamber until tank pressure reads 5 psi.
 - d. Repeat procedure until 2 cans are condensed.
 - e. Close V5, V11 and V14.
 - f. Close V16.
 - g. Open V4.

Day 4

1. Early in the morning of the fourth day, the temperature should be 20-40°K depending on the specimen and the helium level should be close to R_L which is attached to the bottom of the outer can. Retighten heat switch. At this point begin the second transfer and transfer for 1 minute after the level passes R_H using the same

- procedure with valves V15 and V16 as on previous day.
2. Condense 2 storage cans of helium gas at 20 psi into probe helium chamber using same procedure as previous day.
 3. Turn on electronics
 - a. Power switch of guarded data amplifier.
 - b. Power switch of digital voltmeter.
 - c. Power switch of DC current supply.
 - d. Turn on thermometer current and adjust variable resistors so that a negligible current is passing through the thermometer, allowing battery to stabilize.
 4. Return at 5-6 o'clock when the temperature has reached 4.2°K . The helium level should be between R_H and R_M of the depth gauge. Retighten heat switch.
 5. Calibrate the digital voltmeter as instructed in the manual.
 6. With the DC current supply switch off, remove the two current supply leads from the back and short them together. Set the digital voltmeter to read the heater current across the 100 ohm standard resistor. Using the null adjustment switch on the guarded data amplifier, offset

the zero until the thermal emfs are nulled.
Reconnect the heater leads and turn on the DC heater current.

7. Calibrate the potentiometer against the standard cell and set the potentiometer zeros and thermometer current using the potentiometer, nanovoltmeter and the chart recorder.
8. Tighten heat switch and begin third transfer. Transfer in the same manner as before for 6 minutes after the helium level has passed the top resistor R_H .
9. Condense 2 storage cans of helium gas at 20 psi into probe helium chamber using same procedure as before but after condensation do not open V4.
10. Begin pumping on helium bath of metal dewar.
 - a. Close V16.
 - b. Start E-135 mechanical pump.
 - c. Close V15.
 - d. Open V16.
11. After mechanical pump has been on for approximately 5 minutes begin pumping on probe helium chamber by opening V3.
12. Take data from 1.3 to 4.2^oK in the next 12-16 hours. The low temperature data is taken during the night to minimize electrical and vibrational disturbances.

- a. Take data from 1.3 to 2°K first, since later in the evening it will not be possible to reach as low a temperature as is possible early in the run.
13. It is usually possible to take more than 155 data points in one evening in which case the shutdown procedure is as follows:
 - a. Close V3 and V16.
 - b. Open V4.
 - c. Turn off electronics.
 - d. Leave heat switch open.
 14. If it is necessary to run an additional evening, then the same shutdown procedure is used except the heat switch is left closed and steps 8 through 13 are repeated the following evening.
 15. After probe has warmed up then V8, V1 and V2 are closed.

The data taken for a single specific heat data point are shown in Figure D1. The graphical record as shown is obtained on a Leeds and Northrup chart recorder which measures the out-of-balance voltage of the Astrodata nanovoltmeter being used as a null detector for the Leeds and Northrup potentiometer. The time axis of the measurements varies from bottom to top with each inch of chart recorder representing one minute on the time axis. To measure the thermal emfs and to calibrate the chart

Figure D1. Graphical record of a typical specific heat data point.

recorder, the thermometer current is turned off in the measuring circuit. With the potentiometer set on zero and the nanovoltmeter set on the desired sensitivity for the voltage drift measurements, the out of balance voltage across the germanium thermometer is monitored (OV_1). Since this out of balance voltage is due to the thermal emfs in the measuring circuit, this point is used as the potentiometric null point for voltage measurements on the germanium thermometer. The chart recorder is then calibrated for sensitivity by offsetting the potentiometer a small amount and noting the change on the chart record (ΔV_1). This calibration allows the subsequent drift rate to be reduced to the potentiometric null point. In a similar manner the zero current offset (OI_1), which includes the thermal emfs, is monitored across the 1000 ohm standard resistor used to measure the thermometer current and the chart recorder is calibrated at this sensitivity on the nanovoltmeter (ΔI_1). Having accomplished these measurements, the thermometer current is turned on and is measured across the 1000 ohm standard (I_1). The initial drift rate of the specimen (V_1) is then monitored across the germanium thermometer. When the heater current is turned on, there is a large overshoot in the thermometer temperature which drives the chart recorder off scale; therefore, the potentiometer detector button is released during the heating period. When the

heating period is over, the potentiometer is reset to V_2 to bring the chart recorder back on scale and close to the potentiometric zero. The heating time measured on the gated clock is recorded as well as the time integral of the heater voltage as obtained from the integrating digital voltmeter. In addition, the heater current as measured across the 100 ohm standard resistor with the digital voltmeter is recorded on the chart. A further measurement of the current (I_2) and the zeros (OI_2 , OV_2) and the sensitivities (ΔI_2 , ΔV_2) follows each data point.

Hand reduction of the data consists of extrapolating the drift rates to the center of the heating cycle. The remainder of the data reduction is accomplished on a Univac 1108 computer. The data of each specific heat data point is punched on three cards, the second and third cards each containing the zero voltages, sensitivities and currents from the beginning and end of the data point respectively. The first data card contains the initial and final drift rate voltages and the digital voltmeter data.

The computer program reduces the data by reading each successive series of three cards. The thermometer currents and the thermometer voltages at the center of the heating cycle are reduced to the potentiometric null point by using the supplied null points and sensitivities. In calculating the thermometer current, the calibrated value of the 1000 ohm standard resistor is used as discussed in Appendix C. These results give the

germanium thermometer resistance at the beginning and end of the heating period. The temperature equivalents to these resistances are obtained from a table of R vs T by Lagrangian interpolation. The R vs T table contains smoothed calibration data at intervals of $\Delta T \approx 0.01^\circ\text{K}$. The average temperature \bar{T} and the temperature interval ΔT are obtained from the two temperature values. The heater current is calculated using the calibrated value of the 100 ohm standard resistor. The power supplied to the sample, ΔQ , is then calculated as the product of the heater current and the time integral of the heater voltage. This power is corrected for the lead resistance of the heater. Using ΔQ and ΔT , the total specific heat of the assembly is calculated at \bar{T} . The addenda specific heat, which has been measured in an independent experiment and fitted to a polynomial expansion in powers of T, is calculated at \bar{T} and subtracted from the total specific heat giving the specimen specific heat. The data points are then analyzed with a least squares orthogonal polynomial fitting procedure. In this fitting procedure each of the data points is divided by the magnitude of the specific heat so that fractional deviations are minimized, thus giving each data point equal weight. C/T is fit as a function of $\gamma + \beta T^2 + \delta T^4$ and the corresponding values of γ, β, δ and θ_D are printed out along with the percentage deviation of each data point from the smooth curve. The percentage

deviations are then fed to an x,y plotting routine which generates a graph of the percentage deviations versus the temperature. A further option of the program allows the specific heat data points to be plotted with a Calcomp plotter as values of C/T versus T^2 for publication or reference.

Resistivity Measurements

The procedure used for determining the resistivity of a sample is based on the standard four wire type measurement. The sample is mounted on the probe as discussed in Appendix C. The voltage contact separation is measured with a traveling microscope capable of measuring to .0001 cm. Since the contacts have a finite width, the average of the outside and inside readings is used for reduction of the data. Considering the contact finite width, the accuracy of this contact length measurement is 0.5%. The current supply is then attached to the probe and the voltage developed across the voltage contacts is monitored with the digital voltmeter. In addition, the voltage developed across the standard resistor is also measured. The current is then reversed through the sample and the standard resistor and sample voltages are again monitored. The average of the forward and reverse current voltages eliminates any thermal emf's in the measuring circuit. With the current leads on the sample extremities or approximately 3 cm apart and the voltage leads in the middle 0.8 cm of the sample, a

current of 0.5 amps could be used with the sample remaining ohmic. This current produces typical sample voltages of 10 to 100 μv . with fluctuations of $\pm .1\mu\text{v}$. The sample is then cooled to the boiling point of liquid nitrogen and the entire procedure repeated with a subsequent cooling to the boiling point of liquid helium, and another repetition of the measurements. Several measurements are made at each temperature to reduce the error due to voltage fluctuations to a negligible quantity.

In the reduction of the data, the current passing through the sample is calculated using the voltage developed across the standard resistor and the known resistance. Using this current, the resistance of the sample is calculated. To determine the sample resistivity, the voltage contact length is known from the measurements with the traveling microscope. The second quantity required in the calculations, which is the average cross sectional area of the samples, is determined in a somewhat different manner than usual. Due to several reasons, typical mechanical measurements of the two widths of the sample necessary to determine the area produces errors of the order of 2%, since a single width can only be measured to $\pm .001$ ". One reason for this error is the fact that the samples, particularly the binary alloys, are very soft and machining tends to roll a slight burr at the sample edges which cannot be removed without damaging the samples.

When mechanically measuring the width of the sample, this burr always produces an area which is slightly larger than the true average area.

To do away with the mechanical methods of measuring the area another procedure has been adopted. The sample is first weighed, which can be done to 1 part in 10,000 and produces a negligible error. The volume of the sample can then be calculated using the density of the alloy. A discussion of the determination of the alloy density and the resultant 0.5% error is contained in the following paragraphs. The average length of the sample is measured using a traveling microscope. This measurement can easily be made with less than 0.5% error. Using the average length of the sample and the volume, the average cross sectional area of the sample can be determined to 1% accuracy. Using this cross sectional area and the voltage contact length and resistivity of the sample is determined with an error of $\pm 1.5\%$.

The density determination is made by using the atomic weight of the alloys and the lattice constant. In the case of the binary alloys of silver-gold, the lattice constant is quite well known throughout the range of alloying. Therefore, in the binary alloys, the determination of the lattice constant produces a negligible error and the total 0.5% error in the density is perhaps overestimated. In the case of the ternary alloys considered,

there is no available direct determination of the lattice constants which are necessary. Therefore, a least squares fit of the lattice constant data available has been made as a function of the two independent variables of the concentration of gold and silver in the ternary alloy. All of the lattice constant data has been taken from Pearson¹¹ is all of a stated accuracy of at least .05%. Fortunately, most of the data points fall in a region that is close to the desired values. The equation used to fit the lattice constant and the coefficients determined are shown in Table D1. The experimental points could all be fit to at least a 0.1% accuracy and this is the expected accuracy of the lattice constant or 0.3% accuracy for the atomic volume. Therefore it is felt that the total assumed accuracy of 0.5% in the density determination is a reasonable assumption.

In order to test the overall method of the resistivity determination, samples of 99.9999% pure copper and 99.999% pure silver have been constructed and measured at room temperature and the boiling point of liquid nitrogen. The values determined have been compared to these values of White⁴² and are shown in Table D2. The results are within the combined estimated errors. In addition, the close agreement of the binary silver-gold resistivity data with the data of Boes et.al., as discussed in the main text, verifies the procedure.

TABLE DI .

Coefficients in least squares determination of lattice
constant for ternary copper-silver-gold alloys

$$\text{Lattice constant} = a + bx + cy + dx^2 + ey^2 + fxy + gx^3 \\ + hy^3 + jx^2y + kxy^2$$

x = atom fraction of Ag

y = atom fraction of Au

$$a = 3.6149$$

$$b = 0.64517$$

$$c = 0.60007$$

$$d = -.23471$$

$$e = -.15633$$

$$f = -.55475$$

$$g = .059753$$

$$h = .019551$$

$$j = .28558$$

$$k = .23169$$

APPENDIX E. TABULATED SPECIFIC HEATS

The following tables include a tabulation of all specific heat data points used in the analysis of the binary and ternary alloy systems. The computed values of the total specific heat (CTOT) and the addenda specific heat (CADD) are given in the units $\text{mJ}/^{\circ}\text{K}$ along with the values of T^2 in $^{\circ}\text{K}^2$ and C/T in $\text{mJ}/\text{mole } ^{\circ}\text{K}^2$. In addition to the computed values of the specific heat, the smoothed values of C/T are given from the relation $C/T = \gamma + \beta T^2 + \delta T^4$ using the values γ , β and δ as given in Chapter V. The percentage deviations of the computed values of C/T from the smoothed values are given in the last column of the tables. These tables are found on the following pages:
